Gynecological Operations in Relation to Life Assurance.—Arthur E. Giles (*Lancet,* May 5, 1923) finds that about seventy per cent. of patients regain normal health after operations. The highest proportion is found in cases of conservative procedures and of complete removal of organs. Unilateral operations on the uterine appendages show the lowest proportion of complete recoveries, the chances of complete cure being subordinate to the preservation of the functions of womanhood. There are disturbances of the nervous system, shown especially by the memory being affected and in most cases temporary, varying from eighteen per cent of cases where the operation was of short duration to fifty per cent in the case of long operations. There is a risk that further operations may be required, which may be put down at ten per cent, comprising direct sequelæ of the operation and independent conditions in about equal proportions. The risk is greatest after operations for inflammatory disease of the tubes and ovaries; and it is lowest after the operation of hysterectomy for benign conditions. In regard to the expectation of life in cases of operation for malignant disease, the patients must be regarded as bad risks, the possibility of recurrence varying from ten to seventy-five per cent. After operations for inflammatory disease the expectation of life is fairly good, but it is impaired by the possibility of sequelæ. Patients who have had benign tumors removed may be considered as good risks, as the chance of complications that may lead to a fatal result is negligible. The patients who have had operations that prevent further pregnancy have had an adverse factor in the expectation of life eliminated.

Chronic Endocervicitis and Its Treatment.—John William Burns (*Lancet,* October 14, 1922) believes that chronic endocervicitis should be recognized as a distinct pathological entity, apart from endometritis. Any vaginal discharge which makes the patient uncomfortable is pathological and is usually due to chronic infection of the cervical canal. As a positive culture can be obtained in ninety-two per cent. of cases of endocervicitis, the condition is infective; in fifty per cent. of cases, the staphylococcus, either alone or in association with some other organism, is present. The application of various drugs, douching, tamponade, etc., do not reach the infecting agent deep in the lumina of the glands, and therefore can give only temporary relief. Ionization will bring about marked improvement in those cases in which erosion is not present. If erosion is present the only method of curing the condition is extirpation of the lower two thirds of the cervical canal, including the erosion.

Hyperexcitability of the Smooth Musculature of the Female Genital Organs.—Erich Opitz (*Zentralblatt für Gynäkologie,* October 7, 1922) attempts to establish a new disease picture in gynecology, in which he includes many of the long continued and cramplike pains experienced by women in the hypogastrium, in the small of the back, and also in the inguinal regions and which must be attributed to spastic conditions of the smooth musculature of the genital organs. They include also the musculature of the sacrouterine ligament (posterior parametritis), the broad ligament of the uterus (dysmenorrhea), etc. Antispasmodic remedies, like atropine, papaverin, etc., exert a favorable influence upon these disorders, which frequently occur in vegetative neuroses. In many cases the presacral injection of ten to twenty c. c. of a 0.5 per cent. solution of novocaine (injected in front of each one of the sacral vertebral foramina) has given good therapeutic results.

Testing the Patency of the Tubes With the Aid of the Rubin Test.—Josef Novak (*Wiener klinische Wochenschrift,* October 5, 1922) asserts that no woman should be subjected to operation for sterility until she has been given the benefit of the Rubin test. This test affords valuable information in regard to the seat of the cause of the sterility. If the male ejaculation is found normal, if the sexual life of the female shows nothing abnormal (vaginismus, expulsion of the semen, frigidity), if the vaginal and cervical secretions are normal and the uterus of a normal size and in normal position, the cause of the sterility can be localized in the tubes and ovaries, if we exclude those cases in which the apparently normal male and female sexual products do not have sufficient affinity toward each other. If the tubes are patent, the only cause left is a deficient activity of the ovaries or an inferiority of the natural ova. The Rubin test, however, gives no information as to whether both tubes are patent nor does it indicate which one is patent if only one tube is patent. Inasmuch as both tubes usually show analogous changes in case of disease, the information gained by the Rubin test is a distinct advance. The test so far shows that in the vast majority of cases, in which palpable changes are not demonstrable in the tubes and where even the history is negative in regard to a passed salpingitis, the lesion responsible for the sterility is chronic adhesive processes in the ovaries. This test also gives valuable information regarding the prognosis and curative results in the various diseases (septic and gonorrheal inflammations during and outside of the puerperium and in febrile and feverless abortions). It is also a valuable prognostic aid.

Axial Torsion of Ovarian Cysts.—Hugo Sellheim (*Zentralblatt für Gynäkologie,* July 29, 1922) affirms that the torsion of ovarian cystomata or of pelvic tumors results from the transmission of some twisting motion of the entire body to the tumor, which lies in such a position as to be easily twisted, especially when the tumor contents are fluid. Such a motion would be a turning of the body in the upright or recumbent position. The more forceful and the more often the turning of the body and the longer it is continued, as in dancing, the more readily does the twisting of the pedicle occur; furthermore, the more fluid the contents of the tumor, the easier is the torsion of the pedicle. The author illustrates this very forcibly by turning experiments on eggs. The torsion of other organs, such as the tubes, pregnant uterus, spleen and appendix, may be explained in the same manner.

Treatment of Dysmenorrhea.—C. Menge (*Zentralblatt für Gynäkologie,* August 19, 1922) states that it is extremely difficult to cure dysmenorrhea, both the idiopathic form and that of nulliparæ with a small uterus, permanently. The author dilates the cavity of the uterus as much as possible and for a long time, with which procedure he has had good results. The entire uterine cavity is first dilated with Hegar uterine sounds up to size ten and the sounds are pushed upward to the fundus each time; each sound is then left in place for about one minute. A multiple metrotomy of the region of the internal uterine os is then done with a scissorslike instrument devised by Eymer, which is introduced into the uterine cavity closed and its blades covered, and is then withdrawn through the cervical canal in the open position, with the blades exposed. In this way the innermost layer of the uterine wall is incised circularly in about eight or ten places. The purpose of this metrotomy is to avoid the deeper lacerations in the region of the internal os of the cervix and of the entire cervical canal in the subsequent dilatation of the uterine cavity with Hegar sounds up to size sixteen. These larger sounds remain shoved up near the fundus within the uterine cavity, each for about two minutes. Immediately after the last sound has been removed, the entire uterine cavity is tightly packed with xeroform gauze, saturated in oil, up to the fundus and this is left in place for eight to ten days. The oil soaked gauze facilitates the subsequent removal of the gauze.

Etiology and Treatment of Leucorrhea.—Walter Bigler (*Schweizerische medizinische Wochenschrift,* December 28, 1922) discusses the causes of the nonspecific leucorrhea, particularly the dependence of the function of the vaginal wall upon the diseases of the internal organs. Their relationships to the acute and chronic infectious diseases, especially to tuberculosis and to the structure of the normal secretion (glycogen content, acidity) are important. The author restricts his discussion to the noninfectious hypersecretion of the cervical mucous membrane, which is usually associated with a stigmatization in the vegetative nervous system. This nonspecific fluor originates only in the vagina or cervix and never in the body of the uterus. Although the normal secretion shows no high bacterial content, there is no relationship with high bacterial contents. An endogenous factor (a readiness to inflammation) must be effective. Frequently there is only the external manifestation of an internal change: endocrine disturbance, especially in the ovary; other causes are acute and chronic general infections, diseases of the blood and metabolism and constitutional anomalies, such as infantilism and status lymphaticus or hypoplasticus. The bactericidal powers of the vaginal epithelium and blood are important protective factors. Vagotonia may be responsible for this condition. The most important factor in the treatment is the constitutional element but symptomatic treatment is also necessary. The use of sodium chloride and lactic acid irrigations seems to be especially indicated.

Excretion of Urochromogen in Gynecological Diseases.—E. Klaften (*Wiener klinische Wochenschrift,* May 11, 1922) shows that only such bodies in the urine should be designated as urochromogen as show the reaction both with permanganate and the diazo reaction, as only in this way can a definite determination be made. This view is also justified by the fact that it teaches that the body excretes urobilinogen and other indefinite chromogens and aromatic oxyacids, as well as oxyazodyes produced by certain drugs. Bodies which give only the diazo reaction but do not react typically with permanganate and alkali, must not be designated as urochromogen. Practically, it is also important to consider the reaction of the urine when testing for urochromogen and the test should be done on a twenty-four hour specimen, using no less than six c. c. of urine for the test. The urine, diluted 1.5 times, twice, etc., is mixed with two to five drops of a one in a thousand solution of permanganate; if the reaction is negative, no further examination is necessary, but if it is positive, the alkali reaction, the treatment with permanganate after a previous acidification with two to three drops of a dilute acetic acid solution should follow and the diazo reaction should be tested at all times. The author asserts that the urochromogen reaction is not specific and that its appearance in the urine is always to be considered as an expression of a constitutional affection of the organism, without regard to the etiological origin. It has also been shown that it is a valuable reaction in chronic diseases, such as tuberculosis and carcinoma, and in the acute infectious diseases, such as measles, typhoid, paratyphoid, and typhus fevers. A positive reaction in cases of severe cardiac defects, pneumonia, and other diseases is also a bad prognostic omen.

Technic of Internal Examination.—M. Traugott (*Zentralblatt für Gynäkologie,* October 14, 1922) extols the value of rectal examination in obstetrics and gynecology. In obstetrics, the rectal examination should be used when the external examination alone appears to be insufficient; if necessary, it may be supplemented by a vaginal examination. The rectal examination is harmless provided the thumb of the examining hand is kept away from the external genitals. With this maneuvre the examining finger may be passed much higher on the presenting part of the fetus, thus securing a greater palpable surface and, therefore, simplifying the diagnosis; with the vaginal examination, on the other hand, the vaginal vault is an impediment to the advancing finger and the entrance of the cervix by the finger is dangerous. The author prefers to make the rectal examination always at the height of a labor pain. If the amniotic sac is still up high, it cannot be felt. The true amount of dilatation of the soft parts is also determinable and there is no danger of rupturing the amniotic sac. If the presenting part is to be palpated when the amniotic sac is still intact, the palpation should be done at a time when there is no labor pain. If the amniotic sac has ruptured, we can determine not only the true size of the cervix, but also the turning of the sagittal suture following a labor pain at the height of the pain. The indication of an obstetrical operation by rectal examination, especially in multiparæ, is determinable only during the height of a labor pain. Another advantage of rectal examination is the fact that careful sterilization of the hand is unnecessary and also that the examinations need not be limited in number. Other things being equal, the examination during a labor pain is less painful because the pain of the examination is exceeded by the labor pain. If the possibility of mistaking the pulsation of the rectal and vaginal arteries for that of the umbilical cord is borne in mind, such a mistake will be made but rarely. Excluding cases of placenta prævia, the author made vaginal examinations in three hundred labors only in those cases where operative obstetrical procedures were necessary and has never made any important diagnostic error. He has never seen a puerperal infection or injury of the rectum or other organs in a case where rectal examinations were made.

In gynecological examinations, the author introduces the finger, flexed toward the symphysis pubis, into the vagina, and palpates along the lower border of the horizontal ramus of the pubic bone for a distance of three to four centimetres laterally from the centre of the symphysis, until he feels the pulsation of an artery; if the tip of the finger is pressed more firmly against the pelvic wall under the horizontal ramus of the os pubis, the obturator foramen will be felt. The diagnostic value of this examination is as follows: 1. Conclusions may be drawn from the abnormal diameter of the obturator foramen regarding the rest of the supporting genital organs (deficient musculature, thin connective tissue). 2. Thrombi in the obturator veins may be palpated. 3. The possibility of obtaining a nerve pressure point (neuralgia) by pressing against the horizontal ramus of the os pubis. 4. An obturator hernia can be definitely diagnosed. The vaginal palpation of the obturator foramen is possible in every case.

DIABETES.

Treatment of Diabetes Mellitus.—O. Leyton (*British Medical Journal,* April 28, 1923) thinks that there is little doubt that insulin will prolong the lives of those patients who have only a small fraction of the islands of Langerhans functioning. The injection of insulin into a patient suffering from severe diabetes lowers his blood sugar and raises his respiratory quotient. The sugars in the blood of diabetics are not the same as in normal individuals and abnormal sugars can be converted into normal by the action of insulin along with hepatic extract. Man can live fairly comfortably on thirty grams of carbohydrate along with unlimited protein and fat. If a patient with severe diabetes be given enough insulin to ensure his utilizing thirty grams of carbohydrate he will escape the symptoms of diabetes mellitus, but his blood sugar will be above 0.15 per cent. during the greater part of the twenty-four hours, which will cause overstimulation of the small amount of pancreas which he still possesses and gradual deterioration. The final stage will be destruction of the pancreas; then the patient will have to rely for all the sugar burning material on supplies from the outside. In case these fail, life would be extremely short. This is the danger which should be avoided by strictly correlating the diet with the amount of insulin available from the pancreas of the patient, together with that injected.

Insulin and Diabetes: The Present Position.—Henry F. Moore (*Lancet,* April 7, 1923) states that insulin must be given by subcutaneous or intravenous injection, as it is destroyed by trypsin. The dose varies with the case according to the severity of the disease, the body weight, the diet, and so on, and must be controlled by frequent blood sugar estimations in each case, until one learns the amount necessary to keep the fasting blood sugar normal and to abolish glycosuria permanently. The usual plan is to divide the daily quantity into three equal parts, each part to be given just before the three chief meals. Anything from six to fifty rabbit units a day may be required and in some cases of coma one hundred and fifty units may be required within twelve hours. Adjustments in doses are often necessary, because a dose which just controls glycosuria one day may be excessive or inadequate on another. The consensus of opinion is definitely that the insulin treatment of diabetes mellitus will not replace the dietetic treatment, but will be an important adjunct thereto—at least in the more severe cases. Probably the less severe cases will not need the product at all and we shall be able, especially in the nonjuvenile cases, to control the disease by dietetic means alone. Its use, however, in the severe, the juvenile and coma cases, as well as those complicated by severe acidosis, infection and gangrene, will assuredly be a great addition to our present methods of treatment. It is questionable whether insulin should be used at all except by those who can regulate its use by blood sugar estimations, or in threatened or actual gangrene or coma; even then the danger of hypoglycemia should be understood, and suitable measures should be ready for dealing with the characteristic symptoms.

Some Problems of Diabetes Mellitus.—L. B. Winter and W. Smith (*British Medical Journal,* April 28, 1923) summarize the results of their experiments as follows: 1. The normal blood sugar of man and animals has a lower rotatory power than a, B glucose. It is probably of a reactive nature. 2. The blood sugar of diabetics is mainly d, B glucose. 3. A more complex sugar is also present in diabetic blood. 4. In the majority of diabetic cases injection of insulin causes a change in the nature of the blood sugar. The complex sugar disappears and the ratio polarimeter to copper reducing value is altered. 5. Insulin and liver extract together alter the rotatory powers of d, B glucose or d-fructose *in vitro*. 6. Injection of adrenalin into normal rabbits causes the blood sugar to be altered. It appears to become like that of diabetics. 7. An extract of yeast has an effect similar to that produced by insulin, when tested on animals and on diabetic persons. 8. Insulin convulsions in rabbits may be relieved, and the animals restored to normal, by injection of adrenalin.

Administration of Insulin by Inunction.—S. V. Telfer (*British Medical Journal,* April 28, 1923) states that insulin can be introduced into the blood stream by means of inunction. This method of administration necessitates the use of much larger quantities of the drug than those required to produce comparable effects by subcutaneous injection. However, in estimating the effects produced account must be taken chiefly of the duration of the hypoglycemia. A sudden reduction, followed by an abrupt rise in the blood sugar, such as is indicated by cases in which a relatively small amount of the drug is injected, indicates a transient effect. The ideal method of utilization would appear to be indicated by a prolonged period of hypoglycemia maintained by slow absorption. The author's results suggest that advantage might be taken of this method of utilizing crude insulin extracts. At the present time the cost of isolating the drug in a pure and active state, for purposes of hypodermic medication, is such as to restrict its application on a large scale.

Touching for the King's Evil*

By WILLIAM RENWICK RIDDELL, LL.D., F.R. Hist. Soc., etc.

Toronto, Ontario,

The very curious custom of the sovereign "touching" those afflicted with scrofula, or the King's Evil, with a view to their cure, was continued in England until the time of Queen Anne (1). The origin and ultimate reason for this practice can now be conjectured with a high degree of probability approaching absolute certainty.

It is at length becoming generally recognized by all competent to judge that in spite of their fragmentary and disconnected character, popular superstitions and customs are by far the fullest and most trustworthy evidence we possess as to the primitive religion of prehistoric man (2). It is equally true that man is much the same everywhere, no matter what his race and what his apparent advance in civilization: what we have in common with our very remote ancestors is much more important and fundamental than our differences.

"There's such divinity doth hedge a king," said the King of Denmark (3), meaning not that a king had a guardian angel or divinity who protected him, but that there was in a king, as such, a divine nature shielding him from attack (4). He was a king *de facto* only, but that circumstances did not affect the divinity in him. In prehistoric times the adage was considered literally true, the king was the very truth, a divine being, he was a god, a man-god. Being a god, he had all the privileges as such, his person was taboo, no one might touch it without incurring the wrath of the god; his house, his clothing, his food, were all sacred (5), and anyone who interfered with anything of the king's was in deadly peril, however innocently the act might have been performed.

All this seems very strange to our modern minds, but it was not strange to the minds of our far off ancestors or to the prehistoric ancestors of any people—nor is it strange to the mind of the modern savage.

Whatever may be the causes of such uniformity—and the causes are, of course, hidden in the mists of prehistoric time—it is certain that in every region of the world, as soon as we find a nation or tribe emerging from prehistoric darkness into the light of authentic history, we find that the fundamental conception is "the solidarity of the gods and their worshippers," and that society is considered as composed not of men alone but of gods and men. The god is an actual physical father and his worshippers are literally of his stock, he is a king and his worshippers must obey his commands; the man who may become king is also a god with divine attributes and divine power. Moreover "each group had its own god or perhaps a god and goddess to whom the other gods bore no relation whatever." The modern savage in almost all instances is still in that mental state—his king or chief is a god and to interfere with him or anything of his, however innocently, is to invite the gravest consequences.

A New Zealand chief left part of his dinner by the wayside; a slave, a stout hungry fellow, found it and ate it. When informed that the food was the chief's, though he was a strong man in the prime of life, remarkable for courage and had quitted himself well in war, he was at once "seized with the most extraordinary convulsions and cramps in the stomach which never ceased till he died about sundown the same day." A Maori chief lost his tinderbox; several persons finding it used it to light their pipes and died of fright on learning to whom it belonged; "their strength ran out like water" (6). Or if death does not at once ensue, serious and even dangerous disease may follow a transgression, however involuntary. A Tongan attacked by scrofula or induration of the liver knows at once that he has touched the king or some of his belongings (7).

Fortunately homeopathy is the ruling principle in aboriginal sanitation and prophylaxis as in aboriginal medicine; and he who could involuntarily or otherwise smite with disease, could prevent the disease by touching the imperilled transgressor. The Tongan fearing that he has violated the sanctity of his king has a perfect prophylactic in touching the sole of the king's foot with the palm and back of both his hands, and if he has eaten food which he suspects to be tabooed, he sits down before the king and presses the king's foot against his own stomach; as a consequence the food does not swell up and kill him,

and he escapes the "King's Evil" and sclerosis of the liver, all too common among his fellow subjects.

From prophylaxis to cure is but a short step; and it is most probable that a disease caused by touching something belonging to the king was cured by a touch of the king. The ruling principle of aboriginal sanitation was carried into the practice of medicine—homeopathy, like cures like (8). This will probably account for the undoubted fact that the disease known as the King's Evil and curable by the touch of the king was different in different countries. We have seen that amongst the Tongans there were two "King's Evils," scrofula and an affection of the liver. The evidence of language, which after all is frequently crystallized superstition, renders it probable that our own Aryan ancestors had the same view. Among the Romans, *morbus regius* was jaundice—Horace calls jaundice by that name in his celebrated *Ars Poetica* (9). It is quite in accord with this terminology that the kings of Hungary were said to be gifted with the power to heal jaundice (10). It is true that the appellation given to jaundice was otherwise explained: some referred it to the golden color of the skin (11); the favorite explanation, however, was that jaundice was socalled because it was to be cured by delicate remedies, royal enjoyments, *regiis deliciis* (12).

Celsus, who flourished a little before the middle of the first century, prescribed splendid dwellings, rooms, furniture, banquets, games and other more questionable pleasures which exhilarate the mind. According to him it was because these were believed to be beneficial that the disease was called regius, i. e., royal (13). Quintus Serenus Sammonicus, who probably flourished about the middle of the third century, gave the same advice and the same derivation (14). But these were physicians and physicians were and are notoriously rationalizers, and at one time, if not now, *ubi tres medici, duo haeretici.*

The other King's Evil of the Tongan is scrofula, and this disease is apparently the only one known by that name in England and France (15).

That kings down to historical times, even in the most advanced communities, continued to consider themselves and to be considered divine, is beyond question. The Emperor of Rome was "Divus Augustus," always after death and generally from the time of assuming the purple. One of them claimed and exercised the right to marry his own sister as the gods Jove and Zeus did theirs (16). The Pharaohs and the Ptolomies, Kings of Egypt, did the same, some of the ancient Pharaohs, it is said, even married their daughters; the Kings of Persia took over their predecessor's harem, including their own mother, while royal houses of Tyre and Carthage were descended from Baal (the sun) and Emperors of Japan from the moon goddess.

Nor was the gift of healing disease wanting in all. The story of Vespasian when in Egypt—the very home, indeed, of superstition as of civilization—healing a man nearly blind and another with a disabled hand—or in one version, a lame leg, was told both by such a grave writer as Tacitus and by the lighter and gossipy Suetonius (17). The blind man was cured by the saliva of the prince topically applied (18), while the halt was healed by pressure of the prince's foot, just as in the Tonga Islands.

Ælius Spartianus tells us that the Emperor Hadrian restored sight to a blind woman: the same Hadrian when suffering from a fever was touched by a Pannonian born blind and the fever at once left Hadrian while the blind man received his vision (19); and Pyrrhus, King of Epirus, by simply pressing with his foot, splenetics (then a broad term) drove out the disease instantly—but then he had on his foot a big toe mighty with divine power which after his death could neither be consumed by fire nor wasted away by time (20).

It is not to be wondered at that the Kings of England and of France laid claim to the power of curing disease—it is not on record (except in a few instances to be dealt with more particularly hereafter) that they claimed to heal more than one disease—and that, for some obscure reason, now impossible to determine with absolute certainty, was one of the royal diseases of the Tongans, scrofula.

Some assistance may be found in the superstitions of the past and of the present.

The Syrian goddess Atargatis was born of the Euphrates, as her congener Aphrodite Anadyomene was born of the seafoam. She was changed into a fish and thereafter fish were sacred to her (21), one of her types and representatives. Her worshippers believed that if they ate fish, they would be visited by boils and scrofulous ulcers (22).

For a modern example of the same thought, let us go to our own continent. The Elk Clan of the Omahas believe that they cannot eat the elk without boils breaking out on their bodies (23). The Red Maize Clan of the Omahas will have running sores round their mouth if they eat red maize. In Samoa if a member of the Wild Pigeon Clan did not use a certain kind of bread fruit leaves for plates, an eruption like chickenpox broke out over his body. Passing again to the olden times, the ancient Egyptians thought that if a man drank pig's milk his body would break out in scabs; in Japan anyone who wears the Mikado's clothes without his permission will have swellings all over the body; in Fiji there is a special disease caused by eating out of the chief's dishes or wearing his clothes, the throat swells and death may ensue (24).

There was a dispute never decided as to which of the two countries, England or France, could claim the right to prior use. French writers, e. g., the Jesuit Father Superior Gabriel Daniel, in his ponderous *History of France* (1713, new edition 1722), and Francis Eudes de Mezerai in his equally voluminous *History of France* (1643-1651, new edition 1672), as well as Andreas Laurentius (Andrew Laurence) in his *De Mirabili Strumarum Sanatione* (1609), all gave the glory to France and asserted that the Kings of England had the power from the Kings of France. On the other hand, the English claimed the original, nonderivative and first hand power of their sovereigns though, more modest, they admitted that the French kings had also original and equal power. Such were William Tooker (or Tucker), Dean of Lichfeld, a divine of the sixteenth century (25) whose *Explicatio totius Quæstionis de Mirabilium Sanitatum Gratia, in qua præcipe agitur de Solenni et Sacra Curiatione Strumæ* . . . "London, 1597, is an elaborate historical defence of the power of the English kings in curing the King's Evil. John Brown (or Browne), surgeon in ordinary to Charles II and surgeon of St. Thomas's Hospital, London (26), a prolific writer on matters surgical, who wrote *Adenochciradolagia,* an "anatomical chirurgical treatise of granduls and strumes or King's Evil swellings, together with the royal gift of healing by imposition of the hands of our kings of England and France," London, 1684, and many others.

In France we are told the power was conferred by direct gift from heaven upon Clovis the first Christian king "upon his being anointed with the Holy Chrism from which he and his successors obtained the title of 'Most Christian' and with it the power of healing scrofula" (27). Other writers say that Philip I, contemporary with Edward the Confessor, was the first who touched (28), and it is added that he was afterwards deprived of the healing power on account of the irregularity of his life (29). Louis the Fat touched successfully using the sign of the cross" (30).

In England, the common account is that Edward the Confessor (1042-1066) was the first to possess or at least to exercise this power—but there is nothing extant affirming this until the *Gesta Regium* of William of Malmesbury, first published in 1120, fifty-four years after the death of King Edward (31). Before going into the story concerning the cure of scrofula, it will be well to dispose of the exceptional cases referred to above.

William of Malmesbury in his *Chronicle of the Kings of England,* says that Edgar, who came to the throne in 959, sedulously procured the divine love by his devotion; his sanctity was so manifest that "no king either of his own or former times in England can be justly and fairly compared to Edgar." The historian then relates that when Abbot Ailward of Glastonbury opened his tomb in 1052 and found his body untouched with corruption, he profaned the royal corpse by cutting it to fit it into the too small receptacle he had prepared for it. Thereupon "the blood immediately gushed out in torrents. . . . The violator of the sacred body presently became insane and shortly after broke his neck going out of church. Nor did the evidence of the sanctity of the king stay at this, it proceeded further, a man, lunatic and blind being there cured" (32). It is, however, apparent that these miracles were wrought not by Edgar, the king and *quâ* king but by Edgar the saint *quâ* saint; and they do not differ from the miracles at the tombs of other saints in the early and middle ages.

The same remark may not be applicable to the curing of the blind by a king more holy and celebrated than Edgar and who came to the throne nearly half a century after Edgar's death. Of Edward the Confessor, King of England from 1042 to 1066, William of Malmesbury says that he cured six men wholly blind and one man with one eye. The account reads suspiciously like that of Vespasian's cure of the partially blind man in Egypt; but all such marvels have a family resemblance (33).

As to the insanity cured by Edgar, in ancient times, insanity was a well known punishment for sin against the god—the same thing is found among certain tribes to this day (34), and the name is legion of those who were blinded for looking upon a god or upon what was forbidden—from Tiresias who saw the virgin goddess Pallas Athéné in her bath to Peeping Tom of Coventry, who risked both eyes to view the Lady Godiva when she rode through Coventry, clothed only in her beauty and goodness, to secure from her husband, Leofric, Earl of Mercia, a remission of the heavy tax he had imposed upon the people of that ancient city.

These miracles of curing the blind were not continued in the after history of England and I leave them to pursue my main theme, namely, the cure of scrofula.

The account given by William of Malmesbury is the fount from which all others spring. Several historians before him had written the life of King Edward the Confessor—Ingulphus, Abbot of Croyland (1030-1109), who was in the prime of life at the death of the king and who wrote his *Historia Anglorum,* still extant, and Florence of Worcester (? -1118), who lived about the same time and who wrote his *Chronicon ex Chronicis* founded on the earlier Chronicle of Marianus Scotus, a learned and pious Irishman who died 1083 or 1086—none of these mentions the healing power of Edward the Confessor, nor is it attributed to him among his gifts and virtues—*Signa ac virtutes* in the Bull of Canonization of Pope Alexander III.

William says: "Next, I shall now speak of miracles—a young woman having a husband of nearly the same age but without fruit from the union had contracted a loathsome disease—the fluids gathering to excess around her neck and the glands swelling, she was a shocking spectacle. Commanded in a dream to ask the King to wash the parts, she comes to Court and the King himself performing the labor of piety, strokes the neck of the woman with his fingers dipt in water; joyous health follows the healing hand, the lethal scab is dissolved, so that, worms flowing out with the sanies, the whole noxious tumor itself subsides. But as the mouth of the ulcers was foul and patulous, he ordered that she should be supported out of funds of the Court until perfect recovery. Strange as it may seem, it is nevertheless true that before a full week went by a beautiful skin returned without cicatrix, so that you could distinguish nothing of the former disease. A year after, she bare twins and thereby increased the miracle of the holiness of Edward" (35).

This has always been considered a case of the cure of scrofula and notwithstanding the silence of other biographers and historians, I can see no reason to doubt the truth of the story. I venture to think that a flood of light is shed on the whole subject by William's next sentence: "Those who knew the King's life more intimately say that he cured this disease many times in Normandy. Consequently some in our times who assert the power of curing this disease proceeds not from personal holiness but from heredity of the royal family have a false view of the fact" (36).

William claims to state facts of his own time from his own personal knowledge and this claim has always been considered justified. It therefore seems to me that the passage quoted above proves conclusively that it was generally recognized at the time at which he wrote that the kings, or at least some kings of England, had the power of healing scrofula, and a current view was that this power came from royal descent. The conviction that such power existed did not arise for the first time in that age; it must, I think, have been an existing traditional belief handed down, as all such beliefs are handed down from remote antiquity. While it cannot be said that there is any available evidence to prove it, I am confidently of the opinion that the Saxon and Danish kings, predecessors of Edward the Confessor, the Kings of the Heptarchy and the Saxon, Jute, Angle, and Danish chiefs, who preceded them, all exercised the healing gift. Perhaps, it was so much a matter of course that it was not thought worth while to say anything about it: writing was an exceedingly rare accomplishment in those ages, and the printing press was far in the future.

William was a monk and naturally magnified his church and her faithful members. He attributed the royal gift of healing to personal sanctity, which, it must be remembered, consisted, according to his view, in devotion to the church and her ministers and services. He combatted the view of those who thought this magic power was inherent in one of royal descent. Remembering that he wrote in the times of Henry I. and that the English had not been reconciled to Norman rule, it is probable that the absence in the ruling king of the power to cure the King's Evil—we have nothing to indicate that any of the Norman kings even attempted to exercise the sacred power—was used as an argument by the dissatisfied Saxons against the right of the king to rule over them. Already the contention that the possession of this power was an argument in favor of pretension to rightful occupation of the throne, as its absence the reverse, was current among the people of England as it was centuries afterwards. The other explanation, namely, that the Norman Kings, William the Conqueror, William Rufus, and Henry Beauclerk, actually did touch for scrofula and successfully, and that their adherents adduced this fact as evidencing their lawful sovereignty seems to be contraindicated by the circumstance that William of Malmesbury living during their reigns makes no reference to any such touching, although he carefully details the miracles of their predecessor, Edward the Confessor. Whatever may be the explanation, it is obvious that there were two theories, the one ecclesiastical, attributing the power to the personal holiness of the monarch—the other (which was that in later times adopted by the Stuarts and their partisans) that it was due to the descent from rightful Kings and therefore to occupancy of the throne by right of birth. Neither, I think, was the original view, that of Hamlet's uncle, the fratricidal King of Denmark, that the power was inherent in the King *de facto*.

It may be added that Sir John Fortescue, Henry VI.'s Chief Justice (1442), in his treatise *De Naturâ Legis Naturæ,* written in favor of the title of the House of Lancaster against that of the House of York, argued that the Crown could not descend to a female because the Queen is not qualified by the form of anointing her, at the Coronation, to cure the disease. The Yorkist, Edward IV., derived his claim to the Crown through two women—his mother, Anne Mortimer, and her paternal grandmother, Philippa, daughter of Lionel, Duke of Clarence, second son of Edward III. while the Lancastrian Henry VI. claimed by an unbroken descent in the male line through Henry V. and Henry IV. from John of Gaunt, third son of Edward III. The Yorkist claim is in accord with our present view. A similar argument to that of Fortescue was long after advanced by Nonconformists against the Church of England, that is, that it was against the law of God that a woman should be above man in a church as the Queens of England were in the Church of England—the Church of Rome being much more scriptural in that regard. See, e. g., a very curious 12 mo., Boston, Mass., 1768, *A Dissent from the Church of England,* pp. 27-29, 158-161, 280-285. But Fortescue and the Dissenter both failed—Providence was as usual on the side of the heavier battalions.

To return to King Edward the Confessor; that he had the miraculous gift as asserted by Shakspere in the well known and oft quoted passage in Macbeth. But it must be remembered that this play was written in the early years of the reign in England of James I. (37), who was also James VI. King of Scotland, and James was notoriously very insistent upon his divine right to rule, derived from his royal assent—Shakspere's verses may be confidently taken as written in compliment to the king. Malcolm, who had fled from Scotland and taken up his residence at the Court of Edward the Confessor, inquires of the physician (38):

"Comes the King forth, I pray you?
Doct. Aye, sir: there are a crew of wretched souls,
That stay his cure: their malady convinces
The great assay of art; but, at his touch,
Such sanctity hath heaven given his hand,
They presently amend.
Mal. I thank you, doctor.
(Exit Doctor)
Macduff: What's the disease he means?
Mal. 'Tis call'd the evil:
A most miraculous work in this good king;
Which often, since my here remain in England,
I have seen him do. How he solicits heaven,
Himself best knows: but strangely-visited people,
All swoln and ulcerous, pitiful to the eye,
The mere despair of surgery, he cures;
Hanging a golden stamp about their necks,
Put on with holy prayers: and 'tis spoken,
To the succeeding royalty he leaves
The healing benediction. With this strange virtue,
He hath a heavenly gift of prophecy;
And sundry blessings hang about his throne,
That speak him full of grace."

It is of great interest to observe the method of cure. The fingers are dipped in water and then the neck is stroked with the wet fingers. The use of water to anoint the sores seems to be an evolution from that of saliva which was used by Vespasian and others, which use is almost certainly aboriginal. Andreas Laurentius, professor of physic at Montpellier and chief physician to Henry IV. of France, informs us that that king employed his saliva; this was at the end of the sixteenth century (39).

The saliva is by many savage tribes considered to be a part of the man whether he be an ordinary individual or a king or mangod. The saliva of a king is something to conjure with; on the Slave Coast of Africa, in Senegambia, in Ashantee, on the Congo, and in many other parts of the uncivilized world, the greatest care is taken not to allow the saliva of a chief to get into wrong hands (40). There can be little doubt that our Aryan ancestors had the same superstition. The saliva, then, was sacred and had a magic healing power (41).

Indeed, almost anything touched by the king received this mystic gift. The water in which Edward the Confessor washed became holy and shared with him his power to heal the blind, and the water with which his fingers were wetted became equally efficient.

The stroking with the hand is of immense antiquity among many nations (42). We have no record of "touching" in the reigns of the Norman kings, whether they feared a failure by reason of their not coming to the throne by hereditary right, or by reason of their contempt for the superstition, as in the case of Cromwell and William III. in the seventeenth century, or by reason of their unpopularity among the common people. We shall see that the numbers "touched" during Stuart times were almost in proportion to the popularity of the king.

Stephen of Blois and Matilda were, perhaps, too busy to pay attention to such a trifle as the health of the populace; but there seems to be no doubt that Henry II., the first Plantagenet King of England, exercised or at least claimed the gift or had it claimed for him. Peter of Blois (Peter Blesensis), his chaplain, Archdeacon of Bath and later of London, one of the most learned of medieval writers, and one of King Henry's most trusted servants, says of this king, "Not in vain did he receive the sacrament of royal unction of the efficiency of which, if it is unknown or comes in doubt, the disappearance of imaginary disease and the cure of scrofula will supply the fullest proof" (43).

There is no known account of the exercise of this power by the other Plantagenets until Edward I., who is said to have healed 182 persons. That all the kings of England had and exercised this gift, we have the evidence of the celebrated Polydore Vergil in his *Anglicæ Libri xxvi.*

The following is his statement: "King Edward (i. e., the Confessor) by divine gift was accustomed by touch alone to heal the strumous, that is, those suffering from struma. Struma is the disease which Italians in common parlance call scrophula, from scrofæ (i. e., swine), which are afflicted with this evil complaint. It is a humour in which certain deep seated glandlike concretions arise, formed of pus and blood; it creeps through the neck and chest for the most part. A certain perpetual gift flowed as of hereditary right to the later kings, for even now the kings of England cure the strumous by touching them after certain hymns have been recited and ceremonies observed" (44).

It is rather difficult for the modern physiologist and pathologist to enter into the mind of his medieval brother without a full understanding of his terminology. "Humours" were the fluids of the body, real and imaginary, necessary or factitious, natural or pathological; it was upon the due condition, relation, preponderance, "crasis," of the several humours that health and life itself depended. Polydore Vergil did not write until the sixteenth century, however, and his Historia was first printed at Basle in 1534. Writing two hundred years after the event, the accuracy of his information has been much doubted, and even when supported by Hussey it may not be wholly certain.

That Edward I. coined the angel or angel noble (45), a gold coin of the value of 6s. 8d., and gave it to some affected with the King's Evil, there seems to be little if any doubt, and the probability is that this coin was given to those touched for the King's Evil in lieu of the maintenance at the royal expense of the sufferer until fully cured which Edward the Confessor furnished to his patient. The angel was in purchasing power the equivalent of about $50 at the present time.

When we get to Edward III. we are on absolutely firm historical ground. That king claimed the throne of France through his mother Isabel of Valois, and he apparently believed that his claim would be strengthened by the exercise of the power of healing which admittedly was vested in the Valois kings by reason of their descent from St. Louis (Louis IX.) of France. However that may be, he instituted public healings. At these he is believed to have washed the diseased parts with water and given each patient a noble, or according to some accounts, a "touch piece" then for the first time coined (46). The ceremony, simple as it was, was a religious one and accompanied with prayers (47), but there was no formal ritual prescribed, so far as is known.

The practice established by Edward III. was followed by succeeding monarchs, Plantagenet, Lancaster and York, but the first Tudor, Henry VII., made a change. As in the case of Edward III.'s doubtful claim to the crown of France, Henry Tudor's doubtful claim to the crown of England required all the help available. Bosworth Field gave him the throne, his marriage with Elizabeth, daughter and heiress of Edward IV., confirmed him in his seat, but it required all his undoubted ability to secure his retention of it. With all his civil and military skill, the insurrections of Lambert Simnel and Perkin Warbeck showed the danger with which he was constantly surrounded. Divine power evidencing his right to the throne could not wisely be concealed and Henry determined to make much of it. He caused a service in Latin to be prepared —"Ceremonies for the Healing"—and thereafter the simple form of washing the tumors with water was discontinued and a more elaborate and formal ceremony followed (48): "This new ritual was in Latin, the rubric being in English, and was taken partly, with some alterations, from two forms in use in the Roman Catholic Church, the blessing for sore eyes, and the *Exorcismus adversus spiritus immundos.* After confession and absolution, the first Gospel, the same that was ever after retained, was read; during which the sick people were presented by the Clerk of the Closet and touched, the king laying his hand upon the sore places, and were afterwards led away by the surgeon. During the reading of the second Gospel the sick were again presented singly; the sore, or the patient's neck, was crossed with an angel noble, which was then hanged about the patient's neck, to be worn (in the words of the rubric) till they were "full whole." A collect was then said for the sick, the chaplain first saying, *Sit nomen Domini benedictum,* the king answering, *Ex hoc, nunc, et usque in seculum.*

Domine, exaudi orationem meam,
Et clamor meus ad te veniat.

Oremus,—Omnipotens sempiterne Deus, salus aeterna credentium, exaudi nos pro famulis tuis, pro quibus misericordiae tuae imploramus auxilium, ut reddita sibi sanitate, gratiarum tibi in Ecclesia tua referant actiones. Per Christum Dominum nostrum. Amen. And the service concludes with a longer prayer, also in Latin, "to be said secretly after the sick persons are departed from the king, at his pleasure." (48.)

The same form was used by Henry VIII. and Edward VI., but both Queen Mary and Queen Elizabeth made slight changes: "The form used by Queen Elizabeth began with the first Gospel; during the reading of the eighteenth verse, the sick were touched, and retired till the Gospel was ended. The second Gospel was then read; during the reading of the ninth verse, the sick were again presented to receive the golden angel, the queen first marking, as did her predecessors, the seat of disease with the sign of the cross, praying for them and blessing them. The queen and the whole congregation, kneeling, then pray,

Kyrie Eleison
Christe Eleison,

The Lord's Prayer followed, and after it the versicles and responses used in English by Charles II. This prayer was then said, varying a little from those used by Henry VII. and Charles II. Omnipotens Deus, aeterna salus omnium in te sperantium, exaudi nos te precamur nomine famulorum tuorum hic presentium, pro quibus misericors auxilium tuum imploramus ut salute accepta tibi gratias agant in sancta Ecclesia tua per Jesum Christum Dominum nostrum. Amen. The congregation were then dismissed "usitata formula" (49).

Queen Elizabeth had healings very frequently, many thousands being cured by her; it is said the number amounted to three or four hundred a year. Among those touched by Queen Elizabeth was, it is said, a Roman Catholic. He had failed to obtain relief from medicine and as a last resort applied to the queen. Her cure convinced him that Elizabeth was rightfully queen and the Pope's excommunication was ineffective (50). This unfortunate was in prison where he was attacked by the disease. Failing of cure by physicians he applied to the queen and was cured by her touch, but as he was at the same time cured of recusancy, the genuineness of the bodily cure may be doubted. Elizabeth, however, used the sign of the cross and some Roman Catholics attributed the healing to that holy sign, and not to any virtue proceeding from the queen herself (51). It appears that this queen discontinued the practice for a time but if she did she returned to it, and exercised it very frequently and successfully (52).

The sign of the cross was objected to by many in the reign of James I, the first Stuart King of England; the contention of some Roman Catholics, mentioned above, that it was the sign of the cross which had the mysterious healing power gave ground for thought to Protestants and soon James practically discontinued it and ordered it to be expunged from the ritual. It is recorded that the "cure . . . proceeded as effectually, that omission notwithstanding, as it did before" (53). James I and his descendants made much of the "touch" as evidence of divine right to the throne, and if ever a king had a questionable title James was that king—his family had been excluded from the throne by statute and by the will of Henry VIII, his mother, Mary Queen of Scots, had been executed for treason by Queen Elizabeth, and he had been born an alien. As has been well said: "The weaker the sovereigns became, the more solicitude they showed about their title" (54). James undoubtedly believed in the doctrine of the divine right of kings and the Tory party (not as yet dubbed with that name, for the name was not adopted until about 1620) the Cavaliers and the Jacobites, adopted it to the full extent. The gift of healing was one, and a most valuable one, of the indicia of the divine right to the throne: and James and his descendants, kings of England, made the most of it—they did all in their power to encourage "a superstition so politically useful" (55). As we have seen, Shakspere catered to this doctrine of the king in his marvelous *Macbeth,* and the fulsome and nauseating flattery of the translators of the *Bible* shows how far the most intelligent and learned were prepared to go in adulation (56).

The crowds flocking to be healed caused James to issue a proclamation warning off those with contagious diseases (57). "Charles I caused an English form of service to be composed and touched many persons —seventy it is said on a single day at York" (58). The great number of patients had made it necessary to have fixed times for "Healings"; and accordingly stated seasons at Easter and Whitsuntide were provided. These functions were not always in London: Hussey records "Healings" by Henry VIII at Langley, by Elizabeth at Kenilworth, by James I at York, and later by Charles II at Newmarket and other places, by James II at Bath and Banbury, and by Queen Anne at Bath and Oxford (59). We shall see that Charles II sat at the Banquetting House when in London.

Care had to be taken of the sovereign's health. We find in the time of Charles I, a proclamation substituting Michaelmas for Whitsuntide as "more convenient both for the temperature of the season and in respect of any contagion which may happen in this near access to His Majesty's sacred person." This referred to the epidemics frequently prevailing, and the plague and smallpox are specifically mentioned (60).

If not sooner, certainly in the reign of Charles I, the practice was to issue a proclamation fixing a day for a public holiday, and on that day the ceremony proceeded at which all, young or old, rich or poor, and of all nations, might attend. It is said that James I actually touched the son of the Turkish ambassador at the father's request and to such effect that on taking leave of the king the ambassador thanked him for the cure effected (61).

Charles I was executed and the next ruler, king in all but name, was requested to "touch," but Oliver Cromwell refused. It was indeed reported that he had tried but failed. This, however, was a calumny invented by the Royalists when Charles Stuart, son of the dead king, was practising his royal gift at Bruges (62) and elsewhere.

There is no possible doubt that Charles II touched before he came to the throne. "It is certain that the king hath very often touched the sick at Breda, where he touched 260 from Saturday the 17 of April to the 23 of May, as at Bruges and Bruxel, during the residence he made there, and the English assure . . . . that it was not without success, since it was the experience that drew thither every day a great number of those diseased even from the remote parts of Germany" (63). Charles II was a superb politician. There is now no doubt that his chief desire was to reestablish the ancient faith in England but he was determined not "to go on his travels again," and he steadily and constantly courted popular favor on all occasions and by all means at his disposal. When in 1660 he was restored he was only too willing to meet the public expectation of a revival of the rite—the custom was undoubtedly popular during his reign and that of his successor James II. Charles arrived in England late in May 1660 and within a month began to touch for the evil in London. In Samuel Pepys' *Diary* we find the following under date of June 23, 1660: "So to my Lord's lodgings where Tom Grey came to me and staid to see the King touch the people for the King's Evil. But he did not come at all, it rayned so; and the poor people were forced to stand all the morning in the rain in the garden. Afterwards he touched them in the Banquetting Hall" (64).

Curiously enough John Evelyn, the other celebrated diarist of the period, does not seem to have heard of this touching. The first entry in his *Diary* is of date July 6, 1660. "His Majesty began first to touch for the evil, according to custom, thus His Majesty sitting under his State in the Banquetting House, the chirurgeons cause the sick to be brought or led up to the throne where they are kneeling, the King strokes their faces or cheeks with both his hands at once, at which instant a chaplain says 'He put his hands upon them and he healed them.' This is said to everyone in particular. When they have all been touched, they come up again in the same order and the other chaplain kneeling and having angel gold strung on white ribbon on his arm, delivers them one by one to His Majesty who put them about the necks of the touched as they pass whilst the first chaplain repeats 'This is the true light who came into the world.' Then follows an Epistle (as at first a Gospel) with the liturgy, prayers for the sick with some alteration, lastly the blessing; and then the Lord Chamberlain and the Comptroller of the Household bring a basin ewer and towel for His Majesty to wash" (65).

The quotation from Evelyn gives the ceremony followed by Charles II early in his reign: he subsequently made a slight change in the office, and this was followed for the remainder of his reign.

Before giving this form, however, it is well to note that as early as Queen Elizabeth's time, it had been the duty of the royal surgeons to cover any offensive ulcer with a plaster which would conceal the sore although itself with no medicinal qualities. The touched receiving a touch piece of substantial value, when the practice of giving a gold angel noble came to an end, these pieces often found their way to the market and there were frequent instances of the same person presenting himself more than once with a view to obtaining this valuable gift. Consequently, at the very beginning of the reign of Charles I a proclamation was issued on June 18, 1626, requiring a certificate from the minister and church wardens that the applicant had never before been touched (66). This was not wholly effective, certificates were obtained with too great facility with or without improper inducements, and it was found necessary to give more stringent instructions. In the very last month of the reign of Charles II, January, 1683, a new proclamation was issued requiring "all ministers and church wardens to be very careful to examine into the truth before they gave such certificates, and also to keep a register of all certificates they shall from time to time give" (67).

After this proclamation, there were many entries in the parish registers of such certificates being granted (68) but it is almost if not quite certain that many were granted of which no record was kept. The certificate was brought by the patient "to the surgeon in waiting at his private residence. He examined the patients to satisfy himself of the existence and real nature of the disease and countersigned the certificates or gave other tickets to admit to the healing; and it was his duty to acquaint them with the day appointed for the ceremony" (69). The number of those coming up for healing was increased by the practice of some parishes in granting money to assist their sick to London or elsewhere where there was a healing, or conveying them thither at the expense of the parish (70).

The new ritual and ceremonies prepared early in the reign of King Charles II, are as follows (71):

"The Clerk of the Closet, generally one of the Bishops, had charge of the gold distributed at the Healings, and was a check to the surgeons. Under him with the Closet Keeper, who kept a register, under the hand of the chief surgeon, with an account of the numbers who were healed, and received medals; he also gave a receipt to the exchequer for the gold received. He attended the Healings with the gold on his arms ready strung, and presented it to the Clerk of the Closet."

The day being come, which was usually a Sunday, or some other festival, the time generally after morning prayer, the chief officer of the Yeoman of the Guard places the sick people in convenient order. The king enters his chair uncovered, being surrounded by his nobles and many other spectators. One of the chaplains in attendance then begins the Gospel, taken from the last chapter of St. Mark, at the fourteenth verse—the Gospel appointed for Ascension Day. At the eighteenth verse "They shall lay their hands on the sick and they shall recover," the surgeons in waiting, after making three obeisances, bring up the sick in order. The chief surgeon delivers them one by one on their knees to the king, who applies his hands freely round and about their necks; which done, the other surgeon receives the patients from him, and passes them on, to be brought up again to receive the gold.

(*To be continued*).

Lipodystrophia Progressiva Superior

By L. NAPOLEON BOSTON, M.D.,
Philadelphia, Pa.
Associate Professor of Medicine, University of Pennsylvania (Graduate Medical School); Physician to Philadelphia General and Northwestern General Hospitals.

Cases falling into this particular clinical category have been described under a variety of names, but the one clinical term that appears to be generally accepted is that of lipodystrophia progressiva and was suggested in 1911 by A. Simons (1) in his description of this unusual condition.

The first case was published by Barraquer (2) in 1906 and in 1907 Harry Campbell (3) exhibited a typical case before the Clinical Society of London, and this exhibition received a considerable degree of attention. Cases have come from every section of the civilized world. H. L. Smith (4), of Baltimore, in his review of the literature published in 1921, concludes that there are records of twenty-seven well defined cases, twenty-one in females.

Smith gives a report of a case in a female aged thirty-one years and adds a biopsy report giving a microscopic record of the skin changes present. A microscopic study of sections of the skin and the subcutaneous tissue taken from the emaciated areas of living patients has also been recorded by Simon, Feer, Christensan and Weber, and in every instance the absence of fat was a conspicuous factor. Campbell and Feer have mentioned a peculiar odor of the skin.

I have been able to collect from the literature twenty-eight additional cases and am contributing two from my own private practice, bringing the total number of authentic case reports to fifty-eight.

CHARACTERISTICS.

The characteristic clinical features of lipodystrophia progressiva consists in a slowly advancing, symmetrical disappearance of the fat from the subcutaneous tissues (panniculus) of the face, head, neck, upper extremities, trunk and abdomen, as low as the crests of the ilia and upper boundary of the pelvis. Hand in hand with this progressive loss of fat from the upper portions of the body, the hips, thighs and limbs remain normal in size or show an appreciable, progressive increase in dimensions.

Cases furnished by the literature show that approximately one half of them do not conform closely to the foregoing clinical outline, but display many features in common. Limited areas of lipodystrophia, as shown by extreme emaciation of the face, neck or thorax, have been described at length by Betty Shaw (5), Hustler (6), Weber (7), Herz (8), and Johnson (9).

These atypical cases are most often found in male subjects and show considerable variation in the parts of the body displaying fat atrophy. Lewandowsky (10) reported a case with involvement of the face and trunk, while the arms were unaffected. Boissonas (11) and Herman (12) have cited cases where there was no apparent loss of the fat in the abdominal walls, and Laignel-Lavastine (13) and Ward report a case without involvement of the face.

Bignami, cited by Zella, makes mention of a singular observation in a case of lipodystrophia in which there occurred progressive atrophy of the subcuticular fat of the face and upper extremities, also foci of necrosis in the subcutaneous fatty tissues of the lower extremities. The disease in this case began as a nodular tumefaction of the skin, over which there was a change in color to a cyanotic hue, with slowly progressive atrophy. Zella includes as authentic cases reported by Cockane, Lewandowsky, and Laignel-Lavastine.

Lipodystrophia progressiva superior has been suggested as the best clinical term by Gerhertz (14). Some of the case reports refer to the buttocks and lower extremities, as showing an excessive accumulation of fat. One of my patients had reached the age of thirty years, and her hips, thighs and legs appeared enormous in comparison with her emaciated abdomen, chest, and arms; but I take it that this woman's lower extremities were not out of proportion with what the upper parts of her body should be at her age. The lower extremities of this patient are practically the same size as those of her older sister. Illustrations are on record showing many features of asymmetry in different parts of the body. The feet and ankles appear to have escaped involvement.

The clinical description of all cases harmonizes so closely that I am inclined to believe that lipodystrophia progressiva superior will be found more commonly when the profession becomes better acquainted with the clinical phenomena characterizing this malady.

SYMPTOMATOLOGY.

Most of these patients express a general sense of good feeling. Their chief symptom is that they become tired after exertion. The majority of them are forced by their friends to consult a physician on account of their emaciated appearance. These patients may be regarded as eccentric and they display an extraordinary degree of determination. The mind is clear, they are of average intelligence, and the patients I have seen were possessed of exceptional memory.

It is fair to assume that the causal factors in all cases of lipodystrophia, whether typical or atypical, are more or less closely identical. The literature appears to furnish little regarding etiology. Some writers have suggested that it is probably of endocrine origin, while others refer to it as hereditary, some cases having developed after severe fright, while others had as a precursor some acute infection, such as measles, scarlet fever, whooping cough, and other conditions.

A detailed x ray study of the bony structures and the hollow viscera has given negative findings. There are, however, a few reported cases where abnormality of the sella turcica existed. Thus far I am aware of two postmortem reports, but these do not throw any light upon the etiology of lipodystrophia.

Case I.—Miss X, aged thirty-one years, single, height five feet one inch, weight eighty-six pounds. Born in the United States and had always resided in the vicinity of Philadelphia. Saleswoman by occupation. As a child she was rather stout and enjoyed perfect health, until the age of twelve to fifteen years, when friends noticed that her face was becoming unusually thin. This condition did not appear to incapacitate or annoy her until she reached sixteen, when a growing thinness over the upper portion of the chest, shoulders and arms was apparent. Her condition had continued the same as at present for many years. Extreme tiring after moderate exertion was experienced at the age of twenty-five, and her work had become a burden. She was more or less nervous, and experienced dull pains in the lower extremities and through the arms. Sleep did not rest her, although she appeared to sleep well.

There was an unusually heavy growth of black hair over the scalp and a tendency for the hair to extend in front of the ears. It had been cut on several occasions but the growth and amount of scalp hair was extraordinary. Hypertrichosis was seen between the shoulders, where there was a considerable growth of hair, and at the pubic region the female arrangement of the hair was maintained, and likewise the growth heavy. There was a decided growth of hair below the knees, particularly on the calf muscles and this growth extended to the ankles. An uncommon growth of black hair was seen over the forearms, extending to the wrists and backs of the hands. I make special mention of this hypertrichosis because I have not found a case report in the literature where it has been given due clinical consideration.

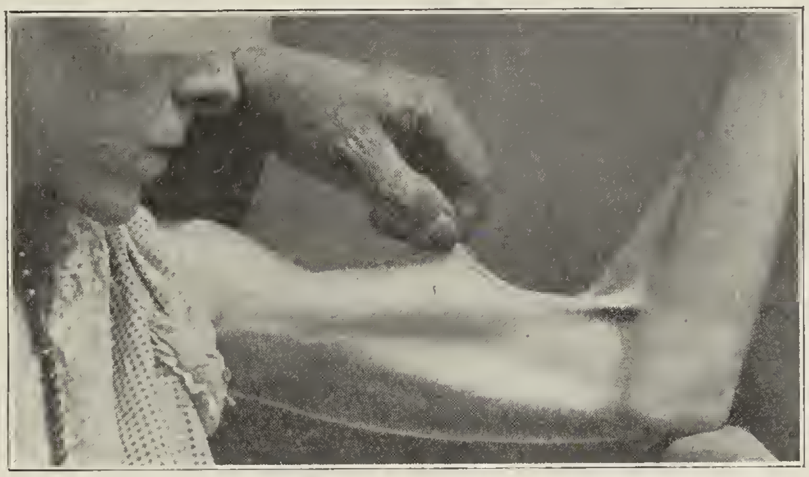

Fig. 1.—Case II. Note the folds of thin skin that can be lifted from the muscles of the arm, and the absence of fat from face, neck, and arms.

Bony structures of the head were normal. Viewing the face from the side, there was to be seen marked depression in front of the ears. The malar bones rose high and there was a pronounced depression around each. The orbits were so prominent that it gave the eyes a peculiar sunken and almost cadaveric appearance. The eyelids were normal, yet the patient did not wink as frequently as was customary in health.

The inferior maxillary and neck regions showed an equal degree of emaciation, and when the patient tilted her head from side to side the sternocleidomastoid muscles stood out conspicuously. The supraclavicular regions were depressed, only as the result of fat atrophy.

When the patient was sitting or standing and one looked underneath the lower jaw, it was noticed that there was an inverted craterlike depression from the margin of the lower jaw toward the base of the tongue. In no other cases of extreme emaciation that have come to my notice has this craterlike appearance been so prominent as it was in this case of lipodystrophia.

The shoulders, arms and hands shared in the extensive degree of fat atrophy. When the patient shut her hand tightly, and contracted the biceps, the muscle stood out prominently and gave emphasis to the absence of fat in the panniculus or subcutaneous cellular tissue.

Measurements of the left arm over the biceps muscle eight inches, near the elbow six and seven eighths inches, at the wrist five and one eighth inch. The right arm gave measurements slightly less than those of the left, which was due to the fact that the patient used her left arm the more. Fat atrophy, while extreme in both arms, appeared to be slightly more advanced in the right than in the left hand. The right hand at the thumb was seven and three quarters and the left eight and one half inches. The palms of the hands were cupped shape.

The chest showed extreme emaciation, which extended to the crests of the ilia, where the fat atrophy appeared to end rather abruptly. Chest expansion was three and one half inches and there was nothing abnormal, except the prominence of the muscles and the depressed interspaces.

The mammary glands were of normal size, but were not covered with fat tissue and on account of the absence of fat, the skin over these glands was shiny, but the gland hung in the manner characteristic of the gland of a woman who has borne many children. Surrounding the nipple was a complete ring that was thinly studded with long black hair.

The reflexes of the extremities were within normal limits, although the knee jerks were rather prominent. The abdominal reflexes were present.

Beginning with the pelvic region, the muscles of the hips, legs and thighs were normal except for oversize. The ankles and feet were normal. There was an abundant development of fat in the panniculus over the hips, thighs and legs.

The skin was pale, but in addition had a peculiar hue. Many patients who saw these two cases of lipodystrophia at my office have expressed themselves in this statement or its equivalent: "She looks like death." This cadaveric appearance is due to the color of the skin (chloasma), as well as to the advanced fat atrophy. The skin was freely movable over the muscles, had a delicate silklike feel, and when taken between the thumb and forefinger could be lifted for some distance from the muscle. Measurements of the lifted skin from the various parts of the body where fat atrophy existed varied from one half to two and a half inches. The fold of skin lifted over the biceps muscle was two and a quarter inches. The skin of the nonaffected areas was normal except for hypertrichosis. Temperature sense for heat and cold was present and the cutaneous reflexes were practically normal.

Percussion over the chest revealed nothing abnormal, the abdominal regions gave negative results. Auditory percussion was employed to determine the apparent size of the heart, liver, stomach and colon, and disclosed no abnormalities.

This young woman completed the common school course. She found no special difficulty with her studies and her record would indicate that her intellect when a child was above the average. She was extremely alert, analyzed keenly every statement made to her and answered questions with undue precision. She read extensively and was well posted upon current events.

Dysmenorrhea had existed since the age of sixteen years, at which time she first noticed extreme emaciation of the upper part of her body. The pain was more pronounced at each period and lasted from one to two days. Menstruation had been profuse since twenty years of age.

During the winter months she suffered intensely from chilling of the hands and feet, and found it necessary to wear heavy woollen garments over the upper part of her body. It was also necessary for her to wear such a garment when sleeping, otherwise she suffered from aching of the arms and chest.

The urine was examined upon several occasions and gave a specific gravity of approximately 1.020. It also contained a small amount of albumin. The quantity for the twenty-four hours was between thirty-two and forty ounces. Microscopic study revealed nothing of special interest.

The blood pressure was always low—systolic 90 to 110.

Following treatment consisting of two grains of whole gland pituitary substance given three times a day, the patient gained five pounds within a period of two months and menstruation, which had always been accompanied by pain, became normal. Treatment was begun on June 6, 1921, at which time she was given the following capsule:

Cerebrin	gr. 2
Strychnine sulphate	" 1/48
Parathyroid	" 1/20
Pituitary (whole gland)	" 1
Potassium citrate	" 2½

This was taken three times a day for a period of fourteen months, at which time the patient had gained seventeen pounds. The accompanying pictures were taken after she had made the seventeen pound gain, and the picture of the arm does not show the characteristic features present at the beginning of treatment.

Fat has been deposited over the face, chest, arms and the entire upper portion of the body. The second picture shows the enormous size of the legs at the calf region as compared with the arms and conveys an idea of the disproportion of the lower and upper extremities. The calf of the leg now measured sixteen and a half inches and the arm over the biceps seven and a quarter inches. Measurement of the arms and hands have increased from one to one and three quarter inches during treatment, and such increase is entirely due to the deposit of fat beneath the skin. The skin now has a normal tonus. At present the circumference of the body on a level at the trochanter is thirty-six inches, and the crests of the ilia twenty-nine inches, umbilicus level twenty inches. Menstruation is normal. Today this woman enjoys health, is mentally bright and states she can do her work without tiring.

CASE II.—Miss A., aged sixteen years, height five feet, weight eighty-six pounds (normal 112). She was born in Philadelphia. Had completed second year in high school. Enjoyed perfect health during childhood, except for typhoid fever, and was exceptionally adapted to her school work. In August, 1921, her parents noticed that her face and hands were becoming emaciated. On July 4, 1921, she still retained her health and vigor, and was able to take part in a foot race (one hundred yard dash), which she won with ease. At this time her weight was 112 pounds. She had always taken an active part in athletics.

There is no evidence of any hereditary taint, and the patient is the second of eight children, all of whom are healthy. Parents are living and healthy. The patient was first seen at my office February 6, 1922.

There was a heavy growth of light hair covering the scalp and an unusual tendency for it to extend in front of the ears and over the bridge of the nose. Growth of hair on the scalp was so unusual that it was cut close when at the age of thirteen years, but when the patient was seen, the hair reached well down to her hips.

There was also present a growth of fine hair between the shoulders, which extended well up on the neck, and this same feature was present below the elbows over the entire forearms. The arrangement of hair over the pubic region was of the feminine type. The hairy covering over the lower extremities between the knees and ankles was practically the same as that seen on the forearms.

The face displayed an extraordinary degree of emaciation and moderate pallor. The malar bones were prominent, there was an unusual depression in front of the ears, the eyes deeply sunken, and the sclera a pearly white.

There was a well advanced atrophy of fat over the lower portion of the face, and an inverted craterlike depression extending from the lower jaw upwards to the base of the tongue. There were numerous areas of pigmentation (chloasma) over the face. The neck was extremely thin, the muscles standing out prominently, as did also the larynx.

This absence of fat was equally prominent over the shoulders, back and anterior surface of the chest. The mammary glands were of normal size for a female of her age, but hung in a pendulous manner such as one would expect in a woman who had completed a period of lactation. The condition of the abdomen was quite like that seen over the chest and the absence of fat beneath the skin extended as low as the pelvis, where it ended quite abruptly. The arms and hands presented an unilateral absence of fat beneath the skin.

The right arm at the biceps muscle measured seven and a half inches, at the greatest point below the elbow seven and a half inches, and the wrist five and three eighths inches. Measurements of the lower extremities were practically normal for her age and weight of 112 pounds. The ankles measured nine and a quarter inches; greatest portion of the calf region eleven and three quarter inches; legs above the knee twelve and a quarter inches, and the thighs fifteen and a half inches. Expansion of the chest by forced respiration was four and one eighth inches.

The hips were apparently normal from the crest of the ilia to the beginning of the femur bones where there was evidence of a rather pronounced accumulation of fat which involved the thighs, buttocks and to a less marked degree the legs. The lower extremities did not present evidence of fat atrophy at any point, and the ankles did not appear to show any excessive accumulation of fat. An x ray study of of the head disclosed nothing of definite clinical interest.

The skin over the affected areas gave an unusual velvet or silklike feel on palpation, and the absence of fat beneath the skin was immediately apparent, while the skin over the lower extremities had a normal feel. It was possible when the patient flexed her arms, so as to contract the biceps muscle, to see this muscle stand out prominently (Fig. 1); and it gave a peculiar hard sensation to the palpating finger. It was possible to grasp a small portion of the skin and lift it from the arm for a distance of one and a half to two and a half inches. The skin of the arms could be rolled over the muscle—the normal sensation caused by fat beneath the skin was absent. Below the knees the skin was rough. The reflexes were practically normal (the knee jerks may have been slightly increased), and the skin reflexes were not exaggerated. Pupils were large and reacted sluggishly to light and accommodation.

Percussion over both chest and abdomen did not reveal any evidence of disease. Auditory percussion gave the size of the heart and the liver approximately normal. The stomach and colon were likewise normal.

During the past two years in the high school, she had stood second in her class. She displayed an unusual amount of determination which history shows has existed since a child.

Upon all occasions the patient insisted that she felt well. She walked a distance of three miles to school and was never known to complain of exhaustion. She did confess, however, after a few months of treatment, that she slept better and upon awakening she felt refreshed by sleep.

There was amenorrhea after the first evidence of her trouble appeared, and this existed until June 29, 1922 (nearly ten months), at which date menstruation appeared and lasted three days. Since June 29th menstruation has been scanty, but regular. There have been present periodical attacks of abdominal pain, which were more or less closely associated with the menstrual period. No evidence of abdominal disease was detected.

The urine was found to contain a trace of albumin upon several examinations, otherwise normal. Examination of the blood revealed nothing of clinical interest, and the metabolic rate showed but a slight increase which might be regarded as due to excitement.

The treatment was practically the same as that given in the case of Miss X——. In this particular instance it was difficult to get the patient to take enough food, but after a few weeks of treatment the appetite improved and during the summer of 1922 she gained seven pounds. She again returned to school, and since her return in September she gained but one half pound.

CASES FURNISHED BY THE LITERATURE.

In view of the small number of reported cases (fifty-six), and on account of the difficulties attending the examination of such records, an abstract of some of these reports is hereto appended.

Reuben and Zamkin, of the Vanderbilt clinic, New York,' have reported two cases of lipodystrophia progressiva, and gave an able review of the literature. The first was that of a girl aged twelve years. For a period of three years the mother noticed a progressive loss of fat from the body, which began first in the face and progressed as far as the pelvis. The buttocks and lower extremities were not affected. This patient had pertussis at four, measles at five, and scarlatina at six years of age, the latter disease being complicated by cervical lymphadenitis, which required incision. The genitals were somewhat overdeveloped for her age. Röntgenographic examination of the pituitary was negative.

In the second case the patient was a girl aged ten years. Her face was becoming gradually thinner, whereas the lower part of the body was becoming more adipose. Her face looked haggard and had a cadaverous expression. Röntgenographic examination of the skull was negative. Both patients were just as active and as strong as normal individuals of the same age. In this condition, Reuben and Zamkin believe there is an hereditary tendency. These writers reviewed twenty-seven authentic reports.

Louis Leipoldt has met with three cases in children while doing routine school inspection, and his reported cases include three males, aged eleven, fourteen and twenty-four years, respectively.

The case reported by Langmead was that of a female seven and a half years old. This patient died at the age of thirteen and the autopsy was made by Weber and Gunewardene, who published their report in the *British Journal for Diseases of Children,* 1919, p. 200. The microscopic report in this case was given by Dr. H. M. Turnbull, and so far as I have been able to ascertain from the literature, this is the most complete autopsy report in a case of lipodystrophia. F. Parkes Weber was interested in this case and a biopsy report of the skin was made to confirm Langmead's original diagnosis. Among the interesting facts in the report are:

1. There was no evidence of any tuberculosis.
2. The child died following an attack of acute mastoid disease with operation and general pyemia.
3. There were present acute nephritis, large septic liver and spleen. These acute pathological evidences were regarded as the result of the acute ear condition.
4. Disappearance of fat from the panniculus was observed over all affected areas.
5. A moderate amount of fat was present at the gluteal regions, orbits, omentum, about the kidneys, heart, pericardium, and under the serous membranes.
6. The thyroid gland was rather large, and microscopic examination showed it to be rich in colloid material. The thymus gland was represented by a scanty remnant. The brain did not display any

evidence of disease. The ovaries, pituitary gland, and suprarenals showed nothing abnormal microscopically.

7. Microscopic examination of the sections and a special report by Dr. Turnbull follows: The sections included a depth of the scalp which under normal condition contains subcutaneous fat, but these did not show such fat. External to the hair follicles in the deeper part of the sections there were a few small areas which might have contained small fat cells and apart from these doubtful areas there was no evidence of fat tissue. The interstitial scalp was denser than normal.

At autopsy it was noticed that the thyroid gland was large and apparently rich in colloid material. The sections studied completed a transsection of a lateral lobe. There was an unusual amount of colloid in the acini throughout the section.

The excess of colloid was associated in some acini with a slight desquamation of proliferated epithelial cells.' The condition of the acini suggested that the gland was in a state of moderate colloidal overactivity. At the same time, as far as can be judged without a special stain, the interstitial tissue was more abundant and denser than in control specimens showing colloidal hypertrophy in children of the same age, and more abundant and denser than in the normal thyroid.

The appearance of the whole section suggested that a moderate degree of oversecretion of colloid was associated with a slight fibrosis and actual diminution in size of the gland.

The cortical cells were small, their cytoplasm stained deeply and displayed vesiculation. Turnbull concludes that the zona glomerulosa and zona fasciculata contained less lipoid than normal for a child thirteen years of age. Retroperitoneal tissue included showed the presence of fat. The ovary revealed nothing abnormal.

The section had been made transversely through the anterior lobe, a small part of the stalk being included. Since the routine procedure was to make a sagittal section through the centre of the gland, he was unable to make use of controls. Further, the method of staining had not differentiated clearly the chromophobe cells from the chromophile, and the cyanophil cells from the eosinophile.

There was an absence of fat from the scalp. Scattering fat cells were detected in one section of the suprarenals. Retroperitoneal tissue contained the normal amount of fat. In none of the sections were there found lobules of embryonic fatty tissue, such as were commonly seen in infants under two years of age. It was to be regretted that the study of the pituitary body could not have been conducted in the manner ordinarily employed by the examiner. Suprarenal lipoid was diminished in the cortical tissue. The presence of an excess of colloid in the thyroid tissues far exceeded that present in females at puberty. No fat was found in the skin or in the panniculus of the arms, scalp and chest. Turnbull suggested that the condition present was pathological and not a phase of normal activity. Further study was necessary to determine the relationship between thyroid changes and fat dystrophy.

Husler reported the first autopsy on the body of a boy aged fourteen, who died during an attack of cerebrospinal meningitis. In this case the fat atrophy was limited to the face; the genitalia were found to be infantile, and there was a persistent thymus. The suprarenals presented a whitish medullary substance, and the cortex of these organs was rich in fat and pigment.

Zella, in his excellent review of the literature on lipodystrophia progressiva, published in 1919, was able to find thirty-six authentic case reports of this condition.

Langmead has reported the case of a female aged seven and a half years.

G. Janson's case was a female of six years, and showed typical emaciation of the face and neck, which did not extend below the umbilicus. The skin was dry and the lymph nodes prominent. This case was not included by Reuben and Zamkin.

Bossert and Rollett's patient was a girl aged eleven years. She began to grow thin in the face, arms, chest and abdomen when four years old, following a severe fright. Lower extremities remained normal and there was abundant fat on the buttocks.

Henry L. Smith, of Baltimore, has contributed the case of a female aged thirty years. Smith cites moderate enlargement of the thyroid, some prominence of the eyes, tachycardia, tremor and hypertension in connection with his case. Mention is further made of a case that was under the care of L. F. Barker and T. P. Sprunt, where increased metabolic rate, hypersensitiveness to adrenalin, and some of the ocular phenomena of thyroid disease, tachycardia, and thyroid struma, were present.

W. G. MacCallum, in a report on the microscopic findings of the skin in the case of H. L. Smith, gives the following: "The epidermis appears to be normal. The epithelial cells are in a uniform layer with normal papillæ of the corium and the normal arrangement of hair follicles. In one section there was a minute area in which the epithelium was somewhat pigmented, and in the interpapillary areas there were groups of pigmented cells. Elsewhere the corium shows no accumulations of cells, except in one or two papillary projections which are infiltrated with mononuclear cells. Most of these are small lymphoid cells, with no granules, but there are a few scattered eosinophile mononuclear cells. Everywhere through the corium, in much greater numbers than in the normal specimens used for comparison, there are twisting and writhing elongated cells which appear to be wandering in the crevices of the connective tissue, especially about the bloodvessels and sweat glands, but also about the sebaceous glands. These have a relatively small nucleus, and an elongated cell body full of basophile granules (mast cells). The corium itself is not abnormal; the elastic tissue fibrils run in alternate directions in successive layers and are well developed. The hair follicles are normal in all respects and the sebaceous glands are quite normal. They contain much doubly refractive fat in large and small globules, which shines with a marblelike lustre under the polarizing microscope. It stains black with osmic acid and red with sudan. Some of it is stained adhering to the hairs as they lie in the root sheaths. The sweat glands are abundant and normal. The tissue just below the corium is extremely loose and is composed of fine, wavy, connective tissue fibrils by no means so coarse as those of the corium, and a few delicate elastic fibrils. There are, as in the corium, bloodvessels and some small nerves which appear to be normal. The deeper layers of this tissue contain more vessels of larger size, of which the arteries show a distinct elastic lamella. The veins show no obvious elasticity, but their endothelium appears to be rather swollen and extremely transparent. No fat is found in the upper layers of this tissue, and it is only in its deepest layers that one encounters several small groups of three or four fat cells which are distended with fat globules. This stains brilliantly with osmic acid or sudan . . . It is not possible to distinguish which of the other cells about these and supplied by the same small bloodvessels are really fat cells, since none of them have any very characteristic form and none contain oil droplets. The fascia does not seem to be abnormal."

CONCLUSIONS.

1. The two patients furnishing the basis for this report have both shown considerable improvement as the result of treatment.
2. In the presentation of this paper it is hoped that the profession at large may be made better acquainted with lipodystrophia.
3. Menstrual abnormalities were present in both cases.
4. Brief notes on typical cases furnished by the literature have been appended.
5. It was impossible to connect clinically my two cases with abnormal functions of the endocrines. There was present, however, some ovarian dysfunction in each case.
6. Abnormality of the skin, including fat atrophy, softness of the skin and roughness of the skin, as well as hypertrichosis, were important factors in the diagnosis.
7. A microscopic study of sections of the skin taken from the affected areas, reveals positive diagnostic evidences.
8. In cases that have gone to autopsy, the thyroid showed an abundance of colloid and mild fibrosis. The suprarenals were deficient in fat in both the zona folliculosa and zona glomerulosa. Husler's case showed a whitish medullary substance and the cortex was rich in fat and pigment. The panniculus and skin were without fat where it normally existed. The thymus was normal in one case and persistent in the other. In males the testes were infantile.

The author's references will appear in his reprints.

Erythema Nodosum Associated with Streptococcic Faucitis

By W. RIDGELY STONE, M.D.,
New York.

The wide prevalence of streptococcic throats during this past spring and late winter in New York and its environs is well known to the profession and easily recognizable. It is interesting to remark the number of these cases which are not associated with involvement of the tonsils, but seem rather to take the type of faucitis, involving the postnasal pharynx and the mucous membranes of the nose, extending even into the Eustachian tubes. The varying severity of these throats has been from a mild faucitis to involvements of the various nerve trunks, and even joint tissues, throughout the body. Just how the toxins or organisms enter the circulation and are transferred to various portions of the body is not to be dwelt upon here, but the two following cases seem definitely to show an association with what was formerly called a rheumatic condition, to wit: erythema nodosum. Erythema nodosum has long since been recognized as a complication or sequela to rheumatic fever. The establishment of the bacterial origin of rheumatism seems to presuppose that all forms of erythema nodosum are due to some bacterial cause. The two cases cited below would seem to bear out most conclusively a bacterial causation in this rather unusual complication of infections. In Case I there is also present a predisposition both hereditary and acquired to tuberculous tendencies, but in this case the outbreak of the erythema nodosum is definitely associated with a streptococcic infection of the mucous membrane of the throat and nose. About two years ago a patient was attacked by a definite rheumatic infection accompanied by an erythema nodosum.

CASE I.—M. F., aged forty-two, consulted me on March 1st because of intense sore throat and rhinitis. The attack was ushered in by usual febrile symptoms and her temperature on the date which I saw her was 102°. Three days later she came to my office with a typical erythema nodosum involving the extensor surfaces of the forearms and legs. This was accompanied by the usual symptoms. She was put on salicylates and alkalines and by May 11th her symptoms had practically disappeared.

CASE II.—E. M. C., male, aged forty-two, came to me on April 27th with a typical streptococcic involvement of the throat and nose, accompanied by a mild inflammatory involvement of the middle ear which was nonsuppurative. That night he was taken with chills and his temperature went to 103.5°. He was confined to his bed for forty-eight hours, at the end of which time he broke out into a profuse sweat and became distinctly better. On the following day pains developed in his ankles and left foot, and he complained of pain in the left calf. On May 1st there were distinct nodules on both legs and forearms. On May 10th there developed a typical bunch of clusters of shingles over the calf of the left leg which was the area where he had previously suffered pain. The eruption was accompanied by pain and burning, but no itching. He was given aspirin and alkalies, and on May 16th was practically ffree from pain throughout the body and, with the exception of general systemic weakness, appeared once more to be normal.

This case exhibits an interesting feature of the association of erythema nodosum and herpes zoster. For a long time it has been my belief that all forms of neuritis have their origin in either trauma or a bacteriemia of some variety. This would seem to be borne out in this case as the focal infection no doubt lay in his streptococcic faucitis.

CONCLUSION.

It would seem more than likely that streptococcic infection of the throat is capable of producing an erythema nodosum; secondly, in Case II, the association of herpes zoster and erythema nodosum gives added proof that both are possibly of bacteriemic origin.

118 East Fifty-fourth Street.

Epithelioma of the Back of the Hand

By DOUGLASS W. MONTGOMERY, M.D.,
and GEORGE D. CULVER, M.D.,
San Francisco, Cal.

Epitheliomata vary in their origin, appearance, and course in each region of the body. From the nature of these growths this is only natural, as they are not adventitious tumors in any sense, but spring from the epithelium of the affected region, and, therefore, partake of the nature of the epithelium in that region.

Most of the epitheliomata of the free cutaneous surface arise from rough patches called seborrheic or senile patches, and most of these patches, with their consequent epitheliomata, occur on the face and the back of hands—situations exposed to light and to the inclemencies of the weather, which undoubtedly influence their occurrence.

The seborrheic keratoses on the back of the hand tend to be much more rocky, more tightly adherent and by far more stubborn to treatment than those on the face. As a compensation, however, it is much rarer for them to degenerate into epitheliomata. When they do so evolve they most frequently form a broad, flattened papule, which grows broader and thicker, and finally the centre degenerates into a granulating, crusted ulcer. Not until comparatively late in its course, however, does it extend downward into the underlying tissues. When it does so extend, the situation becomes very grave indeed, as surgical or cauterant procedures for the elimination of the growth are then almost certain to implicate the underlying tendons and tendon sheaths. It is for this reason that treatment by the electromagnetic energy of radium or x rays is so desirable.

Case I.—A few weeks ago a man, sixty-five years of age, called on us for a condition illustrating well the occurrence of senile patches with a beginning epithelioma. The patches were very hard and tightly adherent, and it was necessary to soak them thoroughly with liquor potassæ before removal with a curette. On the back of the left hand there had slowly developed a circular, red, raised, domeshaped growth one centimetre in diameter. In the middle of its upper surface a vesicle had formed, where undoubtedly ultimately an ulcer would develop. This vesicle probably was due to a streptococcic infection occurring on tissue of low resistance.

The normal history of this growth would be a continuous, slow, centrifugal enlargement with a rounded, advancing border, and some increase in thickness in the pancakelike tumor. As it increased in thickness it would slowly penetrate into the deeper tissues, and would ulcerate on its upper surface. As the tumor in this man's case was in its incipiency it was easily controllable with radium. The radium, by its reaction, caused an exfoliation of the epithelial covering, and then the essential tumor formation was found to be much larger than at first anticipated.

The following four cases are all in the same class as having spread peripherally from a small beginning into large, flattened, ulcerating, tomatolike tumors.

Case II.—A man, aged eighty-four, consulted us on February 5, 1917, for a large epithelioma on the back of the hand which, both on account of its extent and the age of the patient, was inoperable. There was, however, no glandular involvement.

We at first employed radium unscreened as we knew that the thickness of the pathological tissue formed a sufficient screen in itself. Afterwards we screened heavily, thus employing the gamma rays alone, and we combined them with x rays. The growth was slowly receding, and eventually might have cleared up, but the patient died from old age in August, 1917, five months after commencing treatment. This is the subject of epithelioma on the back of the hand shown in Fig. 1.

Case III.—A man, eighty-seven years of age, applied for treatment in June, 1913, for a large epithelioma occupying nearly the whole back of the right hand. The lesion was immovable on its base, the action of the extensor tendons was interfered with, and the fingers were sausageshaped from edema. Although the affection had been present a long time there was no glandular involvement.

An operation, which would have necessitated the removal of the hand, was out of the question on account of the patient's age and general condition. An energetic treatment with x rays had no appreciable effect on the lesion. Radium was not then available. Shortly afterwards the patient died of old age.

The refractoriness to treatment in this case seemed to be due to the thickness of the growth, which acted as an effectual screen against the destructive influence of the wavelets of electromagnetic energy on the advancing base of epithelial infiltration, and we were deterred by the patient's debility and by the proximity of the tendon sheaths from employing ablation or caustics to reduce this thickness.

CASE IV.—A man, sixty-two years of age, consulted us on February 28, 1919, on account of an epithelioma on the back of the left hand four by six centimetres in size. The tendons were freely movable beneath it. After a vigorous irradiation it had decreased to two and a half by five centimetres in eighteen days. It continued to decrease steadily, but more slowly, both in area and in thickness. The end of April he returned to his home in the country, and we did not see him again till the middle of September, when there was still a small residuum of his trouble, for which we gave two vigorous irradiations. Subsequent to this we heard that the cancer had disappeared.

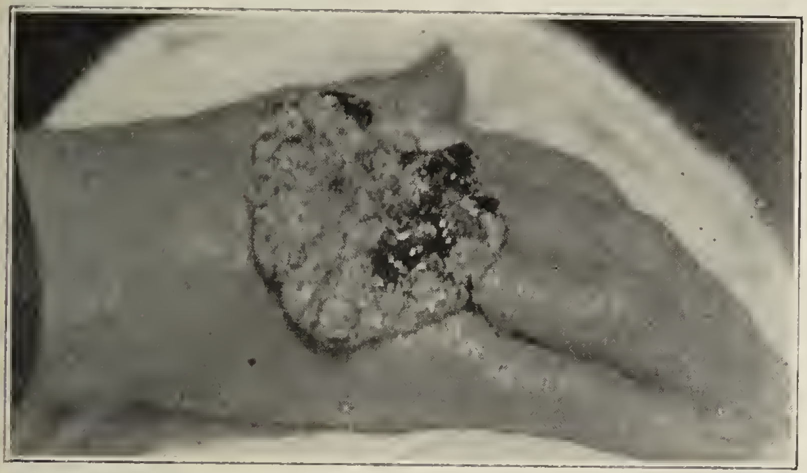

FIG. 1.—Case II. A far advanced fungating tumor with a necessarily grave prognosis. Although it had existed a long time and was very large, there was no glandular involvement.

The two following cases, in addition to being of the large, granulating type, like the two foregoing, are interesting as appearing shortly after an injury.

CASE V.—A man, sixty years of age, consulted us in September, 1917, on account of an epithelioma on the back of the right hand. He said he had been injured there the preceding May, and that the wound had healed in about six weeks. About the first of August the present lesion began to grow, and was now about two and a half centimetres in diameter. The tendons were not involved.

By November, after a thorough irradiation with radium, the epithelioma began to close in gradually, but the centre was still covered by a thick, tightly adherent, yellow coating, and by the end of November there was still a very small unhealed area. We then lost sight of him. In August, 1920, three years after first seeing him, the patient called again for a small wound on the back of the same hand, about which he was anxious on account of his previous experience. This wound healed without incident, and the scar at the site of the epithelioma was now seen to be perfect, with no signs of recurrence.

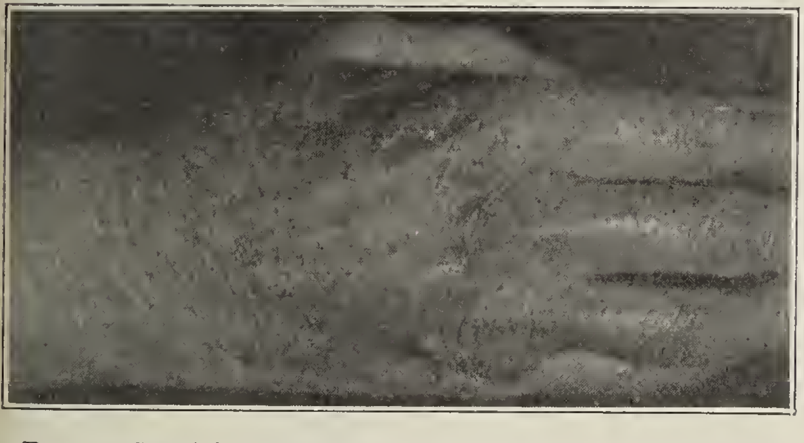

FIG. 3.—Case VI. Shows the small, flat, smooth, pliable scar left after the recession of the tumor shown in Fig. 2.

Cases have been observed of epithelioma following close upon traumatism. For instance, Howard Fox has reported one resembling a granuloma pyogenicum, a lesion which frequently is preceded by a wound, and it is well, therefore, always to think of the clincial resemblance of these two diseases. Hartzell also has mentioned a case in which an epithelioma followed close upon the receipt of an injury.

CASE VI.—A woman, aged seventy, called on June 16, 1922, with a lesion on the back of the right hand, most interesting both as beginning shortly after a traumatism, and also on account of its rapid growth. Curiously enough, about six years previously she had had a growth of some kind on the back of the same hand, which had been excised, and the scar of which was still plainly visible. No pathological connection, however, could be traced between the previous growth and the one under observation.

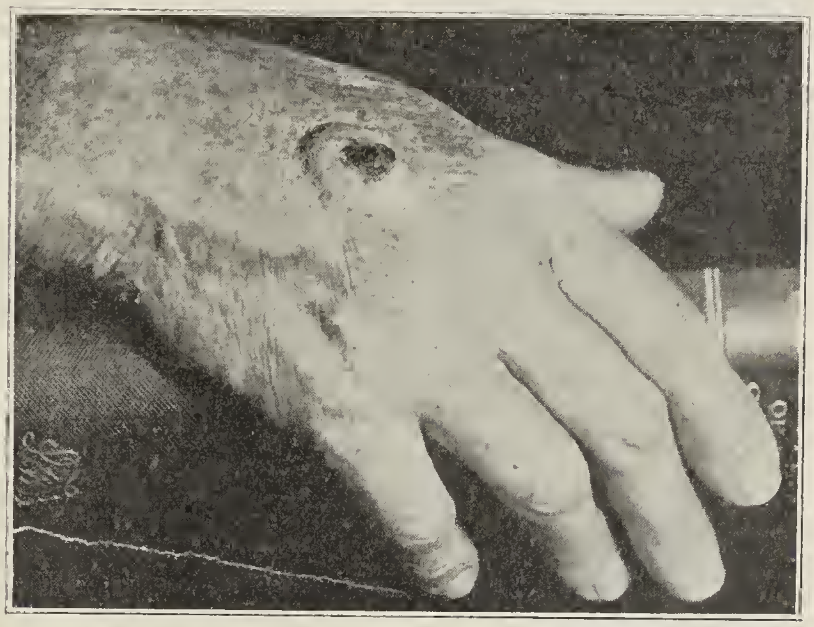

FIG. 2.—Case VI. The most interesting case of the group. This tumor would eventually have developed into a condition similar to that shown in Fig. 1.

The patient said that on Easter Sunday, that is, two months previously, she had skinned the back of her hand by running it against a shelf. The skin was flapped back in a triangular shape, and the wound must have been quite deep, as it was closed by taking several stitches. She said that it had healed with remarkable rapidity.

In about two weeks a lump appeared at the very tip of the triangle, which had grown into the present large tumor. It was a prominent, circular, firm, granulating mass with rounded edges and a flat top, and in the very centre a black crust. It was two and a half centimetres in diameter. It, fortunately, was perfectly movable on its base, showing that it had not infiltrated down between the tendons. It is the subject of Figs. 2 and 3.

Because of its granular appearance, its originating in a wound, and its rapid growth, it had to be differentiated from granuloma pyogenicum, which was perfectly easy in this case. We thought by vigorous irradiation that we might be able to annihilate it, but we were not oversanguine in this, and told her attending physician that a restriction in size down to easily operable proportions might be the best attainable result. We irradiated it by placing thirty-six milligrams of radium directly over the tumor, and also by crossfire by placing sixty-six milligrams of radium in the palm. We gave it exposures amounting to twenty-four hours. Although the radium in the palm was heavily screened a large blister formed. Gradually the growth receded, and in four months the lesion was completely healed, leaving a circular, slightly depressed scar, as shown in Fig. 3.

We consider this one of our best results, the alternative in such a rapidly growing tumor in this situation being amputation of the hand.

The epitheliomata here reported are all of the prominent, broad, flattened variety, differing decidedly from those usually seen on the face. Their consistence is firm, due to the tightly packed infiltrating epithelial cells with very little connective tissue framework, of which they essentially consist. They bleed easily because the bloodvessels and the connective tissue strands in which the bloodvessels run are so delicate. The molecular necrosis and ulceration of the substructures is, however, late. In none of the cases, though some were of long standing, was there any glandular involvement. In two of the cases the growth followed a traumatism; in one of these so closely as to be designated a direct sequence.

The susceptibility to the influence of the rays of electromagnetic energy, whether produced from a Crookes tube or from radium, was not nearly so prompt as is usually met with in epitheliomata of the face. This contrast was especially great as against the epitheliomata of the eyelids, which react particularly favorably to this treatment.

Plastic Surgery of the Face and Neck*

By J. EASTMAN SHEEHAN, M.D., F.A.C.S.,
New York.

Plastic surgery is an increasingly widening expression. It may be described as constructive surgery, in contradistinction to destructive surgery. Plastic operations restore and repair ravages caused by accident, disease, old age, and congenital disfigurements, and the methods of treatment may also be used for cosmetic purposes. It is not my intention to describe *in extenso* any of the many plastic procedures, but I shall bring to your attention the rapid and marvelous strides this branch of surgery has made within a short period of time. I am sure you will agree with me that no other branch of surgical work has made such progress within recent years as has plastic surgery.

It was my good fortune to be associated for several years with Major Gillies, at Sidcup, England, where this branch of surgery, under his direction, has been highly developed with extraordinary success.

The war afforded the surgeon undreamed of opportunities for plastic operations. Those surgeons whose names were well known to all of us before the war, and who performed reconstructive operations, suddenly found that their well known methods were of limited value in meeting the avalanche of unusual disfigurements of face and neck. In order to accomplish the plastic repair of these *mutilées,* newer methods were evolved and the older ones either discarded or improved. Thus at Sidcup, as a result of the methods successfully applied in the treatment of large numbers of cases, there was developed a School of Plastic Surgery, which quite surpassed in technic the methods and treatment (admirable though they were) of any institution to be found in any of the other allied or belligerent nations. The brilliant successes at this hospital were made possible principally by the introduction of the tube pedicle flap of Gillies, and in the use of the Thiersch graft introduced by Esser of Holland, and modified and improved upon by Pickerill, Gillies and Waldron, whereby ephithelium could be supplied to cavities, sulci and exposed raw surfaces. These methods undoubtedly constitute a permanent contribution to plastic surgery.

I shall not attempt to describe to you the technic of making a tube pedicle, for I am quite sure it is now familiar to all of you. Much has been written about it, but I should like to impress upon you the fact that our experience has taught us that the pedicle should not exceed eight inches in the male and six inches in the female and in children. It is essential that the original blood lymph and nerve supply of the pedicle flaps should be maintained through the pedicles. The pedicles are so formed that the bloodvessels running into the transplant remain uncut until after the pedicle has fully served its purpose.

The next feature of the plastic surgeon's work to which I would draw your attention is the method known as rhinoplasty, i.e., the formation of a new nose out of tissue derived from another part, in place of one destroyed by the ravages of disease. While the total loss of the nose from accidental causes resulting from civil occupations is not usual, such loss from disease is not uncommon, and is, therefore, a condition which the special surgeon may be called upon to remedy in the course of his ordinary practice. It is essential in performing a rhinoplasty that an adequate lining, a proper support to the bridge and a covering be supplied. The reconstruction should conform to carefully modelled patterns.

The recent rapid progress in our knowledge of the bone graft, as a means of repair for fractured

---

*Delivered at the annual meeting of the Medical Society of the State of New York, October 21, 1922.

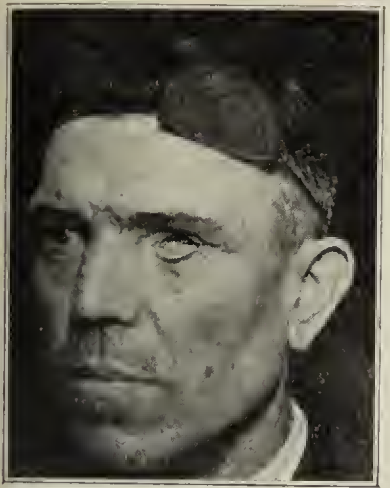

Fig. 1.—Ectropion of lower lid with marked scarring of the conjunctival cul de sac.

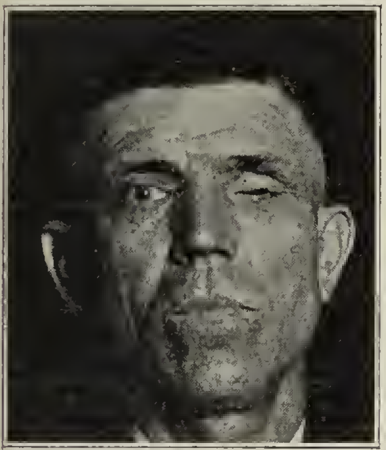

Fig. 2.—Repair of ectropion.

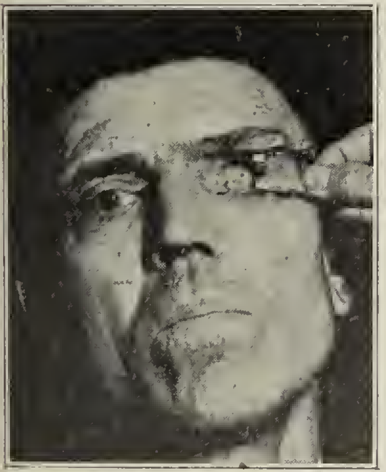

Fig. 3.—Complete epithelization of the conjunctival cul de sac.

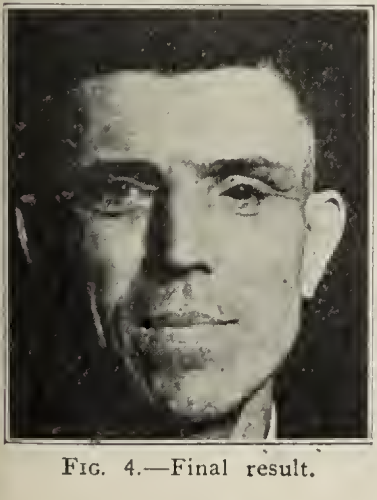

Fig. 4.—Final result.

jaw, has been mainly due to the efforts of such men as Albee, of America, and Gilbert Chubb and Percy Cole, of England, whose experience covers a large number of such cases. The graft is taken preferably from the ilium. This source has several advantages. The size of the graft is practically unlimited. All sclerosed and uncertain bone can therefore be freely removed from the jaw fragments. The soft and vascular nature of the iliac crest facilitates the manipulation of the graft and its subsequent union and consolidation. By varying the position of the iliac crest it is possible to obtain a graft of a general curvature suitable to each particular case. There is little, if any, postoperative disability.

In the treatment of burns plastic surgery finds one of its widest fields of usefulness. Motor accidents, factory and other explosions bring into our hospitals many distressing disfigurements which can now be successfully treated by the latest improvements in skin grafting. I do not mean by this that perfection has been attained in the treatment and successful repair of these cases, for the deformities and disabilities resulting from contractures following severe burns still present a puzzling problem. By fair and constructive criticism and development of present methods, others in this field will undoubtedly advance the plastic treatment of these deformities to a stage where complete success will be the usual result. Even now it is quite possible to graft new eyelids and eyebrows to replace those which have been burned.

With men, in the reconstruction of the upper lip the disfigurement may be covered with hairy tissue obtained from the scalp or similar tissue taken from the nearby regions. With women, the problem is a more difficult one, as many times it is necessary to use a combination of several methods, such as the French, the tube pedicle flap, and the Thiersch graft. Colored spots in the newly formed lip resulting from the transposition of tissue may be rendered white by the application of sulphate of zinc.

Plastic surgery includes within its sphere cosmetic betterment and the treatment of conditions traceable to traumatic, pathological and congenital causes. It has a proper place also in the cure of disease, for example, the epithelization of mastoid and nasal sinus cavities and epipharyngeal contractures as a result of syphilis. Moreover it may be applied to the preservation of function, as in the epithelization of the tonsil sulci. Although it may not be quite in order to make the suggestion, nevertheless I desire to record my belief that the cure for endocervicitis, if its etiology is of a local nature, lies in the epithelization of the parts.

A word about socalled cosmetic surgery as so frequently practised by those who call themselves beauty specialists. The practices of these disgraces to our profession, though apparently successful at first, seldom result in permanent improvement but rather in increased disfigurement, and the consequence of the methods employed by them, for instance, the injection of paraffin is frequently manifest in a general impairment of the health of the patient.

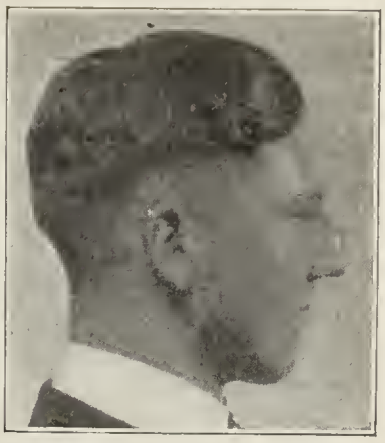

Fig. 5.—Hump nose before operation.

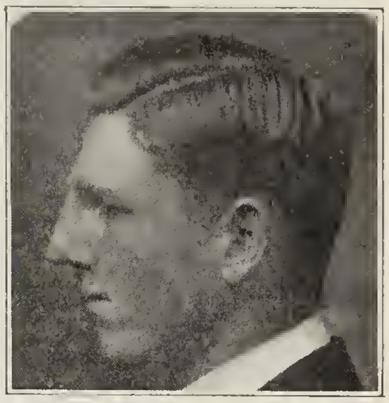

Fig. 6. — Hump removed through columella incision.

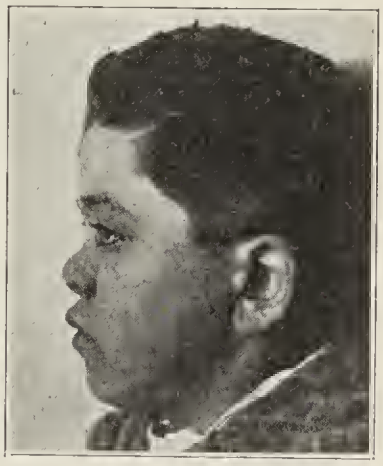

Fig. 7.—Traumatic saddle nose.

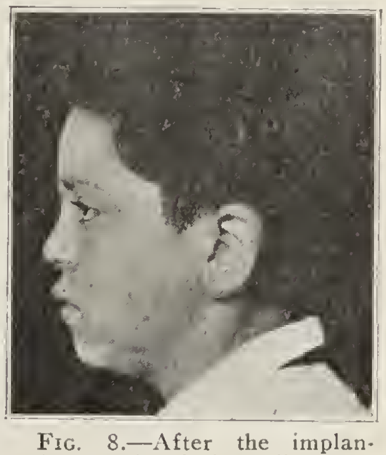

Fig. 8.—After the implantation of chondral cartilage.

The time is not far distant when hospitals must create departments of plastic surgery, placing it upon a sound footing as a separate and distinct branch of surgical work. Postgraduate schools must provide the facilities for men eager to learn the principles of this branch of surgery. Plastic surgery is not easy to master. It requires a thorough operative knowledge, imagination, patience, tenacity of purpose, courage, originality, the feeling of an artist and deftness of hand.

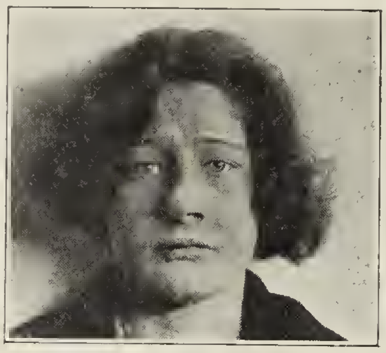

Fig. 9.

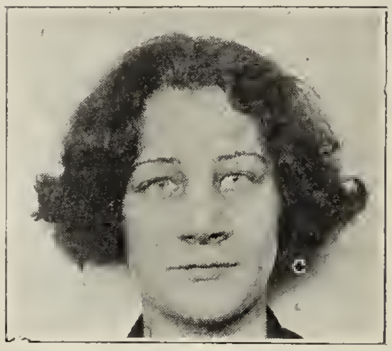

Fig. 10.

Fig. 9.—Deflected nose.

Fig. 10.—Final result. Correction of the external deflection of the nose and the removal of the nasal septum through the columella incision of Sheehan. (One sitting.)

The plastic surgeon must frequently consult, for the attainment of his best results, the dentist, the sculptor and the artist, for reconstruction should be planned on true, feasible and artistic lines. Not only must the injured member, nose, jaw or lip, be restored, but the restoration must harmonize with the patient's facial characteristics and conformation. A cast and photograph of the patient is carefully examined and compared with previous photographs, and the advice of the sculptor or artist is obtained before the restoration or repair is attempted.

In a sense, the sacrifices of the men who fought in the late war are placing upon humanity an additional obligation, for the experiences secured in treating the mutilations and ravages of that conflict are establishing for the benefit of others the methods by which may be successfully treated those disfigurements which heretofore have ruined the lives of men and women, who, conscious of their repulsive appearance, have avoided the company of and shunned contact with even those who were dearest to them, have discouragingly abandoned the attempt to realize their ambitions, and in consequence become morose and misanthropical. A wonderful change is accomplished when the disfigurement or defect is remedied. He, who was the object of his own contempt and the loathing of others, recovers his selfrespect and finds that his importance in the eyes of others has returned. Opportunities for contracting desirable alliances, both business and matrimonial, are restored. In short, what was a pitiable spectacle is changed into a normal member of society, deterred neither by his own consciousness nor the repugnance of others from becoming a desirable member of the community in which he resides, nor from assuming all the obligations of husband or wife, father or mother, or citizen having a part to play in the accomplishment of the destinies of the State.

A glance at the photographs will show that after the successful restoration of the patient he assumes a more cheerful countenance and is better dressed and groomed. It is apparent that he desires to look well, being undoubtedly stimulated in this desire by the contrast between his present condition and his previous terrible state of hopelessness. His aspect of life has changed for the better and the operator himself is thrilled by the results obtained through this merciful branch of surgery.

24 East Forty-eighth Street.

Skin Diseases and Metabolic Disorders*

By OSCAR L. LEVIN, M.D.,

New York,

Instructor and Chief of Clinic, Department of Dermatology and Syphilology, Cornell University Medical School and Clinic; Adjunct Dermatologist, Mount Sinai Hospital; Associate Dermatologist, Montefiore Hospital.

The skin is an important organ of the body, performing certain functions, some of which are essential to life. An intimate relationship exists between these functions and those of the other organs of the body. A general disturbance may result in diseases of the skin, or a skin affection may be the starting point of internal disorders; or both the skin and internal organs may be simultaneously affected by endogenous and exogenous factors, such as bacteria, toxins, drugs, chemicals, and physical agents. It is, therefore, readily seen how difficult it is to state positively whether the skin condition is the result of internal disease, or the causative factor producing a general disturbance.

Metabolism signifies the chemical changes which substances undergo when brought into contact with the living cells of the body. Two factors are involved: catabolism, or reduction of higher to lower compounds, and anabolism, the building of complex substances from simpler ones. As a result of these chemical changes life is sustained.

New and improved methods of investigation are enlightening our conceptions of disease; great advance is being made in our knowledge of the pathological metabolism of the general body economy. Our literature on the subject of metabolism in dermatology, although much increased of late, is, however, by no means complete. The conclusions reached by different workers are not in entire accord. Improvement in the methods of technic in biochemistry, microscopy, functional tests, serology, and other laboratory studies, as well as close and intelligent clinical observation and interpretation, will confirm or disprove our present views, most of which are tentative. Knowledge of this nature

---

*Read at the October, 1922, meeting of the Eastern Medical Society.

gives one a clearer outlook on the etiology and treatment of the different dermatoses.

In this paper I shall not consider the cutaneous diseases or lesions which are recognized as external expressions of infectious, constitutional diseases, such as the exanthemata, typhoid, typhus, syphilis and tuberculosis. Neither shall I discuss parasitic skin diseases like scabies, pediculosis and ringworm, nor infections like impetigo and ecthyma. Even in the groups mentioned above there seems to be some metabolic condition which predisposes the integument to the development of the type of lesion. I shall also omit drug eruptions, although there seems to be some relation of the general economy to the skin which predisposes it to the eruptions. Some have ascribed this to an idiosyncrasy, others to anaphylaxis, but sufficient knowledge is not available to explain this susceptibility.

This exclusion leaves only dermatoses which occur with disorders of metabolism such as diabetes and rheumatism; dermatoses in which metabolic disorders are often found, such as acne vulgaris and seborrhea, and finally, dermatoses such as erythema multiforme and leukamids in which toxic products of metabolic disorders seem to be causal. In all these conditions the skin is apparently attacked by the products of the faulty metabolism by way of the vascular, nervous and glandular systems acting upon the nutrition, the innervation, the secretion and physiological growth and repair of the skin.

Acne vulgaris appears about the time of puberty and persists through that period of life during which the gonadal functions are coördinated with the other metabolic activities of the body. Other evidences of an endocrinal relationship are the recurrence of pustules, especially on the chin, during or about the time of the menstrual period, the increased severity and number of lesions about the same time, and the frequent association of hyperthyroidism with acne vulgaris. Menstrual complaints and uterine disorders are often found to accompany the condition. Montgomery and Culver cited disturbances of metabolism found in goitre as causative. In our series of twenty-two cases in which the basal metabolic rate was determined we found a slight increase in twenty.

The eruption is always aggravated by constipation and a diet rich in carbohydrates. Schwartz, Heiman and Mahnken reported hyperglycemia in acne vulgaris, Levin and Kahn showed that hyperglycemia or a high normal blood sugar accompanied over fifty per cent. of their cases. The blood sugar curve was normal in all the twenty-three patients who were studied for their carbohydrate tolerance; but the renal glucose threshold was lowered in four, and the feces from nineteen showed carbohydrate fermentation.

In 1919 Schwartz, Levin and Mahnken found a mild or moderate state of acidosis in acne vulgaris. Sweitzer and Michelson, in 1920, found no marked or consistent change in the alkali reserve in this condition. Since then we have continued our investigations in collaboration with Kahn and have found a mild form of acidosis in about one third of the cases.

It is recommended that local x ray therapy should be accompanied by a diet low in carbohydrates, anticostive and general tonic measures, alkalies and extracts of internal secretions when indicated.

Rosacea is most common in women at puberty, during the menstrual flow, during pregnancy, and in those with uteroovarian disease. It is always worse in individuals who suffer from gastric hyperacidity and constipation, and who use hot, irritating and stimulating foods and beverages immoderately. Johnston reported the association of gastrointestinal derangements, particulaarly hyperacidity and intestinal fermentation, in rosacea. He also showed the presence of hyperacidity in premature alopecia and in a peculiar form of acneiform dermatitis. This differs from acne vulgaris in that it appears ten to twenty years after puberty and is seated about milia rather than comedones, and from rosacea in its occurrence chiefly on the forehead and line of the jaws and in the absence of telangiectasis.

Darier has applied the term keratosis to a condition of the skin which most of us recognize as seborrhoea. For its etiology he regards direct heredity, or the influence of poor health or bad hygiene of the parents, as constituting the fundamental conditions. The establishment of the genital functions and sexual disturbances on the one hand, unhygienic diet on the other, in the form of hypernitrogenous diet, abuse of stimulants, coarse food, insufficient mastication, abnormal fermentation and constipation are common factors. This condition predisposes to seborrheic eczema, acne vulgaris, rosacea, premature gray hair, and in the aged to seborrheal warts and senile keratoses.

Barber and Semon remark that seborrheic individuals are characterized by an acidosis, as is evidenced by the hyperacidity of the urine and the reaction to treatment by alkalies. Schwartz, Levin and Mahnken detected a lowered alkali reserve of the blood in seborrheic eczema. Levin and Kahn corroborated the presence of acidosis in seborrheic eczema.

All disorders which reduce the general vitality predispose the skin to eczema. Blondes with their dry and thin skins show eczema more frequently than brunettes. The dry skin of diabetes mellitus and insipidus also predisposes to the condition. Towle, Talbot and C. J. White found in acute infantile eczema that the stools showed indigestion of the fats and sugars. Czerny considered infantile eczema evidence of an exudative diathesis occurring in overfed infants, with fat intolerance. Numerous writers cite the frequent complication of eczema in gout and rheumatism. White states that, in the great majority of patients with chronic eczema, anaphylactic phenomena to one or more foods may be found. Johnston was of the opinion that the causation of eczema was due to a derangement of the nitrogen metabolism, and possibly due to protein splitting in the blood stream before the tissues selected their store of amino acid nitrogen.

In our investigations in eczema we found that in mild cases there were no disturbances in the chemical composition of the blood nor in the condition of the hydrogen ion concentration of the body fluids. In eczema accompanied by other metabolic derangements the deviation of the blood chemistry was due to the metabolic diseases. In the latter cases conditions of acidosis were noticed. In severe diffuse eczema we observed a state of acidosis, an increased ethereal sulphate fraction in the urine, indicative, perhaps, of intestinal putrefaction, but otherwise a normal blood chemistry. A certain number of breast and artificially fed infants show eczema as a result of food anaphylaxis. Removal of the offending food from the mother's or infant's diet often clears up the inflammation.

Among the various factors which have been mentioned as causative in psoriasis are gout, rheumatism and renal disease. Schamberg is of the opinion that psoriatic patients retain nitrogen. Johnston and Schwartz found no recognizable disturbances in the nitrogen metabolism in cases of psoriasis. In collaboration with Kahn I observed no change in the blood chemistry so far as the nitrogen disturbance was concerned. A number of the patients showed a mild state of acidosis. A remarkable increase was noted in the nonprotein sulphur of the blood. The administration of a diet low in proteins is rarely of therapeutic value. Thyroid is at times of benefit in the treatment of psoriasis.

Among the many causes mentioned in the etiology of the erythemas are toxemias, rheumatism and visceral disorders. In some of our cases we have detected abnormal figures in the chemistry of the blood, but these were explainable by the general condition present. Some of the cases are anaphylactic in nature.

Urticaria is frequently an anaphylactic phenomenon. Other factors, like constipation and proteid sensitization, may be causal. Toxemias from metabolic disorder in general diseases like Hodgkin's disease and leucemia may express themselves externally in the form of wheals, urticarial papules, and prurigo. Dysfunction of glands of internal secretion, the thyroid, and especially the adrenals, predispose to the condition. Poor sympathicotonus may be detected in almost every case of urticaria. In prurigo of children, which is regarded as related to urticaria, relief may be obtained by the administration of thyroid. It is possible that changes in the colloidal chemistry of the tissues, especially in faulty calcium metabolism, may play a rôle in the production of urticaria.

Purpura, another member of the group of exudative nonvesicular dermatoses, is encountered in association with metabolic disorders like rheumatism, cancer, tuberculosis, nephritis and diseases of the blood forming organs.

Dermatitis herpetiformis at times seems to be an anaphylactic phenomenon. Winfield reported four cases associated with glycosuria. Menstrual disorders, pregnancy and the puerperal state have been cited as causes of the disease.

Pruritis has been recognized as occurring in practically all diseases of metabolism, particularly in diabetes. For the intense pruritus of pregnancy and puerperium a diet low in proteins and the employment of ovarian extract alone or combined with thyroid, are recommended. For the treatment of pruritus and nothing acts so well as reducing the carbohydrates in the diet. Another obstinate type of pruritus accompanies endocrinasthenia.

In almost every case of xanthoma an increased cholesterin content of the blood may be detected. Xanthomas may occur in diabetes mellitus, and in diseases of the liver and biliary system. In one case under observation repeated examinations have revealed a cholesterin content of over 500 mg. to each 100 c.c. of blood. In a case of multiple xanthomata a cancer of the head of the pancreas was discovered.

Leucemia and Hodgkin's disease may involve the integument in the form of infiltrations, nodules, and tumors showing the microscopic characteristics of these diseases, or as erythema, urticaria, prurigo and purpura.

Sycosis vulgaris, furuncle and carbuncle constitute a group of pyogenic skin infections which are caused by staphylococci in individuals often showing disordered metabolism as in diabetes. General debility and diabetes predispose to their development. Hyperglycemia, carbohydrate fermentation and acidosis accompany almost half the cases.

It is not an easy task to indicate positively relationships between dermatoses and disorders of the endocrine glands. The field is still a virgin but a rich one. There is much hard work ahead and plenty of it for those who are undertaking these investigations, but the ultimate results are bound to be most happy. In order to be brief the skin diseases and symptoms which have been described in dysfunctions of the most important glands will be presented in tabulated form.

THYROID

rosacea
lipomatosis

In this outline a brief presentation has been made of our knowledge concerning the relationship of the different dermatoses to metabolic disorders. Our minds, in the search for the truth, will confirm or disprove tentative opinions. In conclusion it is emphasized that it is very well worth while to remember that dermatology cannot be divorced from general medicine and that the data presented here have been of practical aid in the treatment of the dermatoses.

63 WEST SEVENTY-THIRD STREET.

The Grading of Epitheliomata and Their Radiation Sensibility*

By REX DUNCAN, M.D.,
and E. D. WARD, M.D.,
Los Angeles, Cal.

In over one hundred cases of epitheliomata in our institution during the past year, we have been able to make certain histological studies both before and after these tumors have been exposed to irradiation. Microscopic sections were made before radiation in order to determine, first, the degree of activity of the malignant cells, and second, to ascertain the particular cell type. After radiation, sections were studied at fixed intervals in order to determine the histological changes that had taken place.

Before entering into a discussion of the microscopic structure of the epitheliomata mention will be made of their gross salient features as they have routinely occurred to us. These neoplasms present many variations in size, shape and consistency; they may be ulcerated, flat, elevated or depressed, and the surface may be a greyish, pinkish, brownish, or black color. They may be moist, smooth, dry or scaly, and they may start in a small crack, ulcer, scale, leucoplakia or papilloma, or any portion of the body surface or in its orifices.

A more strict definition of epithelioma means a tumor composed of epithelium without any distinction relative to malignancy or benignancy. If we are to consider the specific cells lining the alimentary tract, and comprising the sebaceous, sweat and salivary glands as epithelium, then all the socalled carcinomata are also epitheliomata.

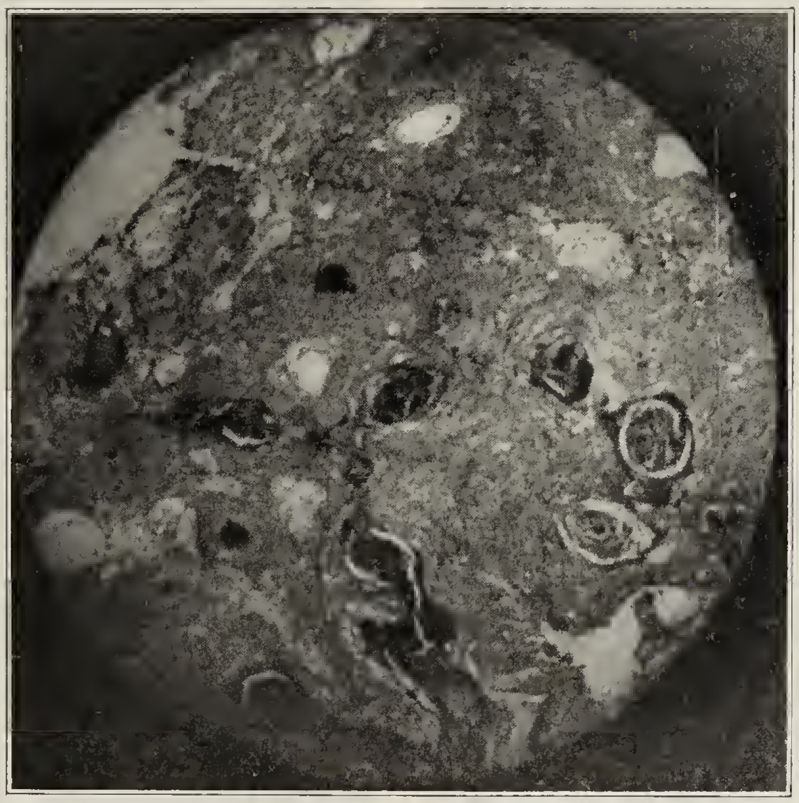

Fig. 1.—Acanthoma.

STRUCTURAL VARIATIONS

Structurally, the epitheliomata may fall within the following apparent types, which are the result of variations in origin and cellular differentiation: 1, Squamous cell epithelioma (Figs. 4 to 11); 2, melanoepithelioma (Fig. 2); 3, nonmelanotic melanoepithelioma (Fig. 6); 4, basal cell epithelioma (Fig. 3); 5, adamantine epithelioma, and 6, mixed cell epithelioma.

This discussion will be confined to those tumors composed of the skin and its appendages and since a large majority of the epitheliomata are of the squamous cell variety, it is this type of tumor with which we propose to deal here.

As its name indicates, the squamous cell epithelioma is composed largely of the cells of the squamous cell variety. These squamous cells may be made of many protoplasmic processes, some of which are seen connecting the cells. Hence we get the name of spindle or prickle cells. Other squamous cell epitheliomata may show many variations in size, shape and growth characteristics of their cells; some may show a marked tendency to cornify, that is, to approach closely the adult epidermal layer of the skin, especially those inside the cheek, lip, floor of the mouth, skin, etc., while those of the cervix, urinary bladder and antrum rarely do so. We see also mixed cell varieties, some of which resemble a round or spindle cell sarcoma while other varieties resemble morphologically all layers of the skin.

GRADING.

The most important factor with which we have to deal in epithelioma seems to be the degree of cellular activity. A great many epitheliomata show a marked tendency to differentiate, that is, to produce a growth whose cells resemble closely the normal. The pearl formation or pearly body is an example, and it corresponds to the horny layer of the epidermis. Other epitheliomata show no differentiation whatsoever, and in the large majority of the latter there are numerous mitotic figures. The more an epithelioma tends to differentiate, the lower is its degree of malignancy. Conversely, the more embryonal or more undifferentiated the cells, the higher the degree of malignancy. Upon these facts, Broders, in 1919, classified epithelioma of the lip into four grades or groups, and since that time he has extended this grouping to cover squamous cell epitheliamata in general. His plan of grading dependent upon the degree of cellular activity, is briefly as follows.

If an epithelioma shows about three quarters of its structure differentiated epithelium and about one quarter undifferentiated epithelium, with no mitotic figures and no socalled one eyed cells, it is graded I. (Figs. 4 and 5). If the percentage of differentiated and undifferentiated epithelium are about equal, with an occasional mitotic figure and one eyed cells, it is graded II. (Figs. 6 and 7). If the undifferentiated epithelium forms about three quarters and the differentiated about one quarter of the growth with numerous mitotic figures, it is graded III. (Figs. 8 and 9). When there is no tendency for the cells to differentiate, it is graded IV. (Figs. 10 and 11). The number of mitotic figures and the number of cells with large, deeply staining nuceoli, socalled one eyed cells play an important part in the grading. With some experience a definite picture of each grade becomes fixed in the mind and little difficulty is encountered in their classification. It must be remembered that not all cells with large, deeply staining nuceoli are malignant; however, when these cells are formed in a neoplasm in large numbers it is best to treat the tumor as malignant or premalignant. These cells are unquestionably regenerative and since malignancy is a regenerative destructive process, their presence is suggestive of malignancy.

---

*Pathological Department of the Radium and Oncologic Institute.

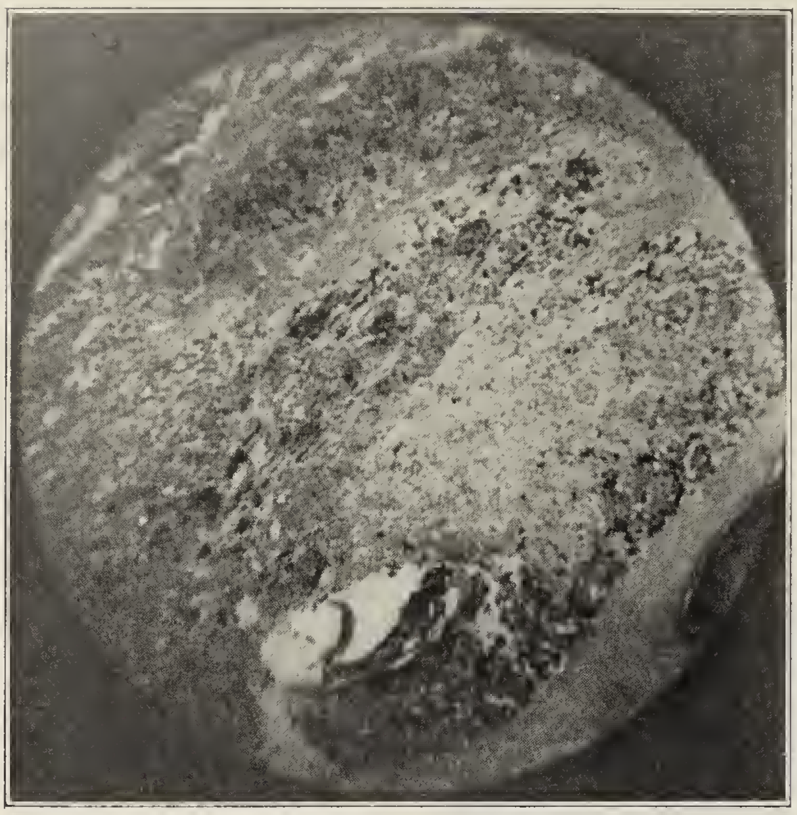

FIG. 2.—Melanoephithelioma.

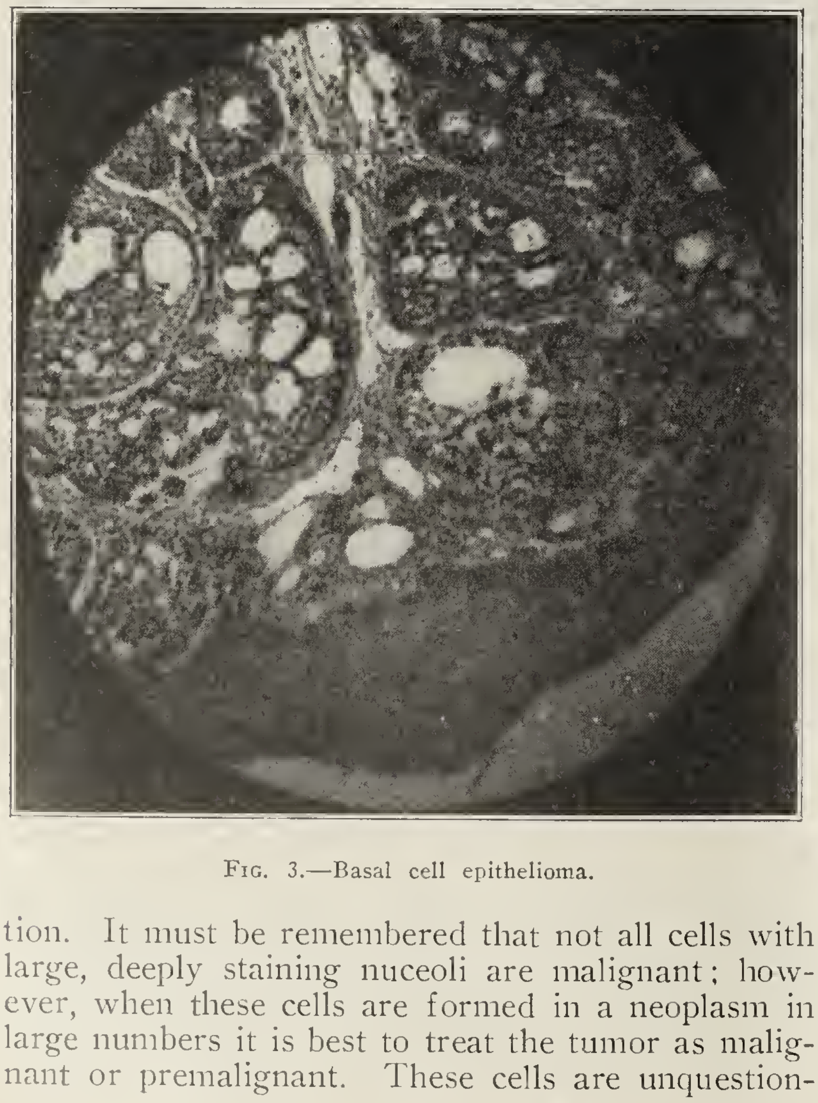

FIG. 3.—Basal cell epithelioma.

BIOLOGICAL EFFECTS OF RADIATION.

The mode of action of cancer cells to radiation is now in the process of investigation by pathologists, from both clinical and histological viewpoints. The specific physical agent is believed to act first upon the newly formed or embryonal cell, at the same time exerting a restraining and later destructive influence upon the sources of blood supply to the new growth. While these forces are acting, nature calls forth reparative processes and the result is a prolification of connective tissues. If the intensity of

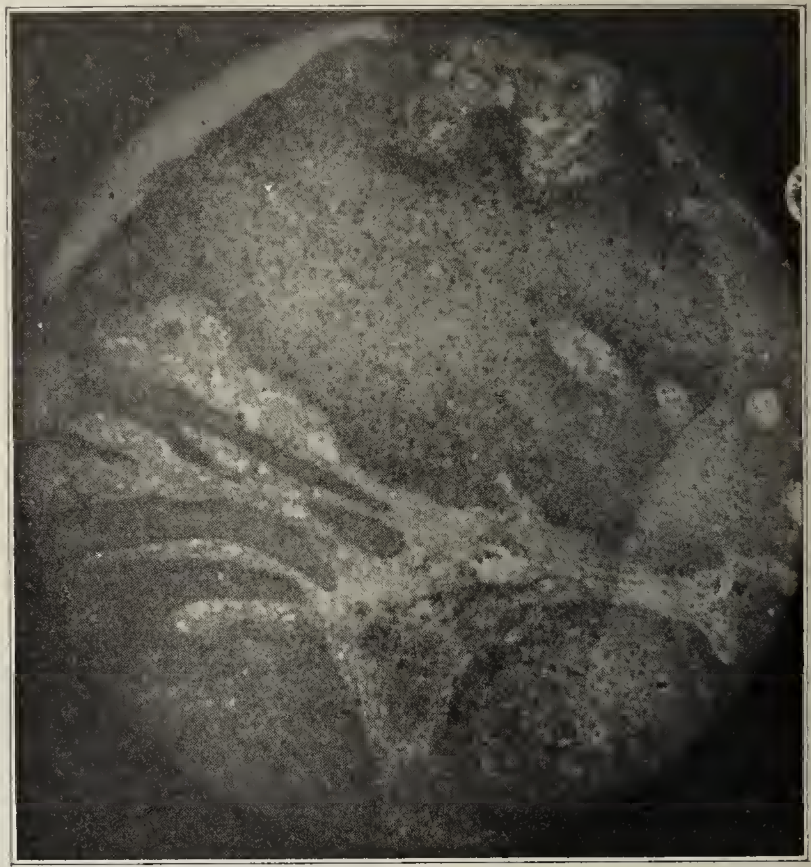

FIG. 4.—Squamous cell. Grade I, low power.

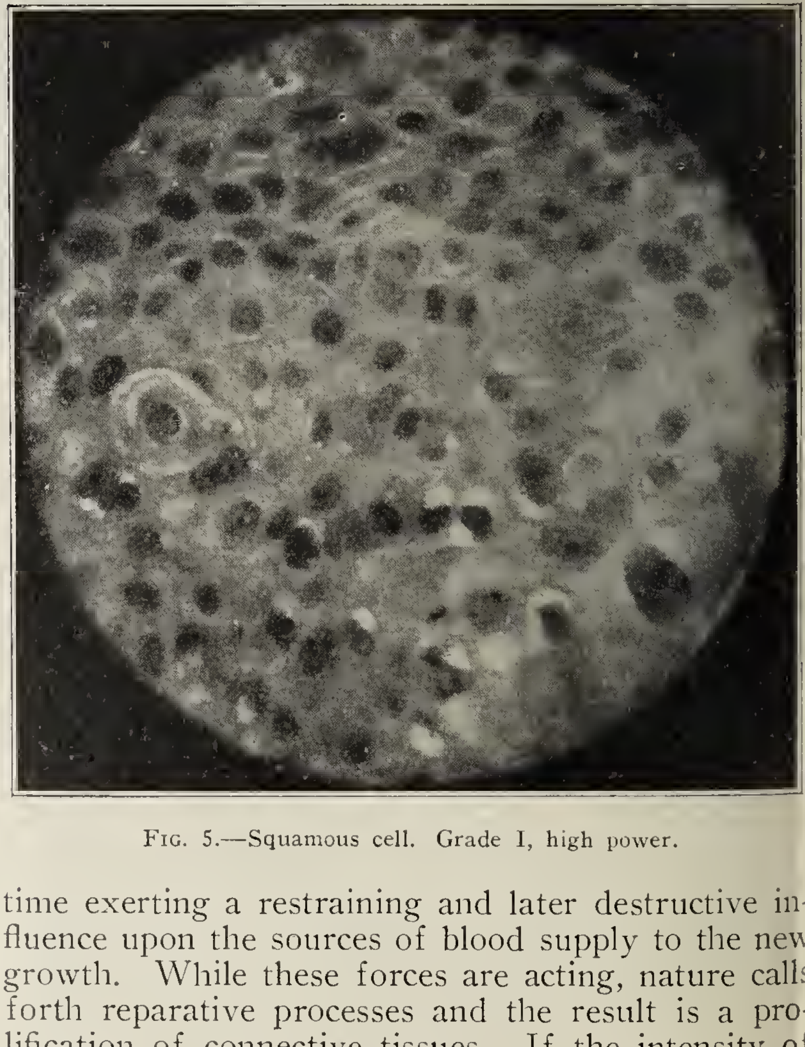

FIG. 5.—Squamous cell. Grade I, high power.

radiation is insufficient, the cells may be rendered dormant only temporarily, while if too intense, may be broken down and nature's resistant properties destroyed.

The difference in sensitiveness of cancer cells to radiation depends upon first, their age, the momentary period in which they happen to be; second, the age of the host; third, the histological species in each case. It is a universally accepted law of radiation that the more undeveloped, embryonal, and undifferentiated the malignant cells, the more sensitive they are to radiation.

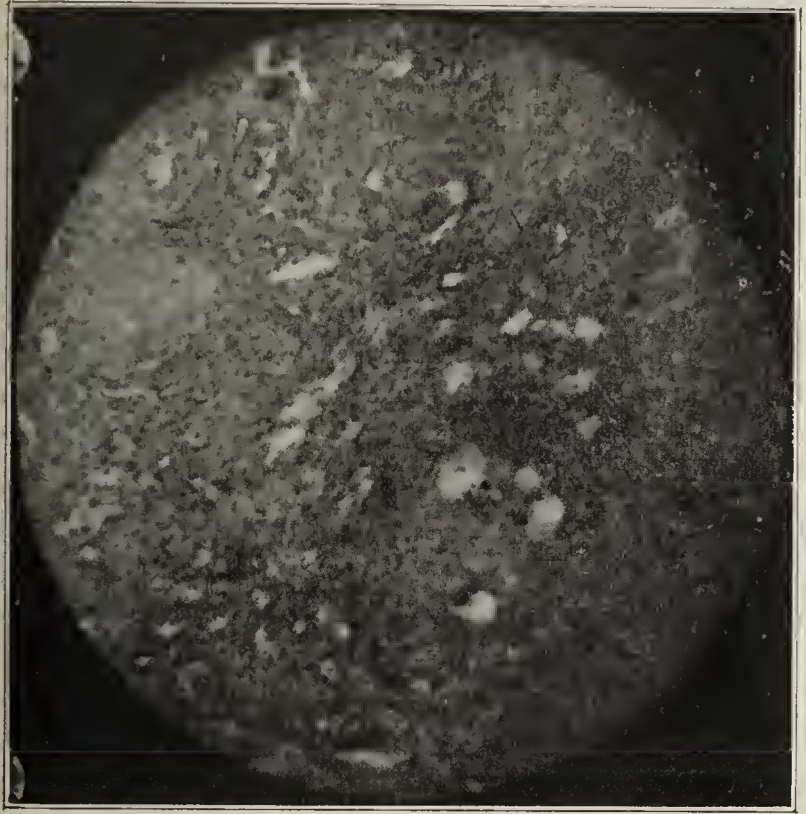

Fig. 6.—Squamous cell. Grade II, low power.

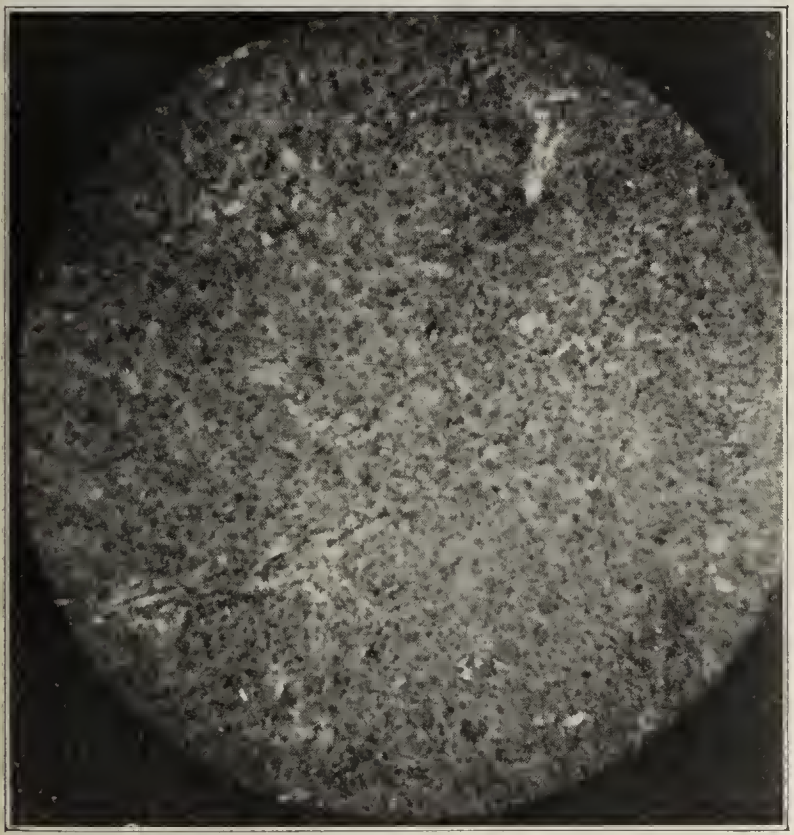

Fig. 8.—Squamous cell. Grade III, low power.

HISTOLOGICAL CHANGES.

The histological changes produced in the cancer cells, as a result of irradiation, are shown in the illustrations. It will be seen that these changes are similar for all four grades, and that the difference lies largely in the degree of sensibility. Grade one is the most resistant, while grade four is the most sensitive, with grades two and three occupying intermediary positions. The specific cell changes following irradiation seem to be as follows: within a few days we have observed a general hyperemia of the tissues, with a beginning of exudation of lymphocytes and polymorphonuclear neutrophiles. In the second stage all the surrounding tissues are more or less swollen. (Second to third week.) The nuclei of the tumor cells are swollen and homogeneous and the entire section is beginning to appear structureless. The cell bodies are enlarged and the cells

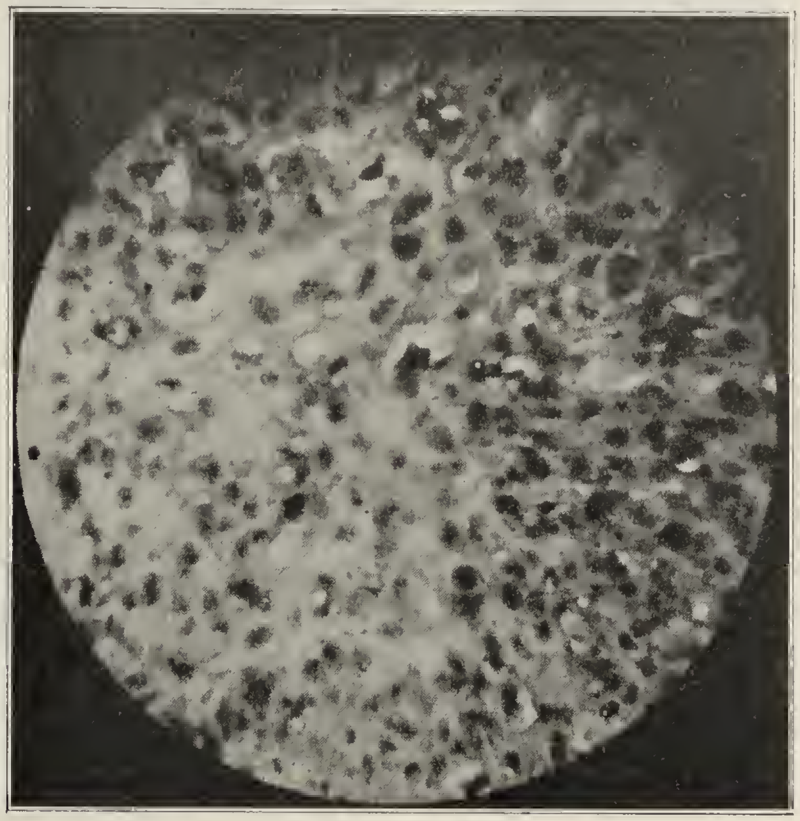

Fig. 7.—Squamous cell. Grade II, high power.

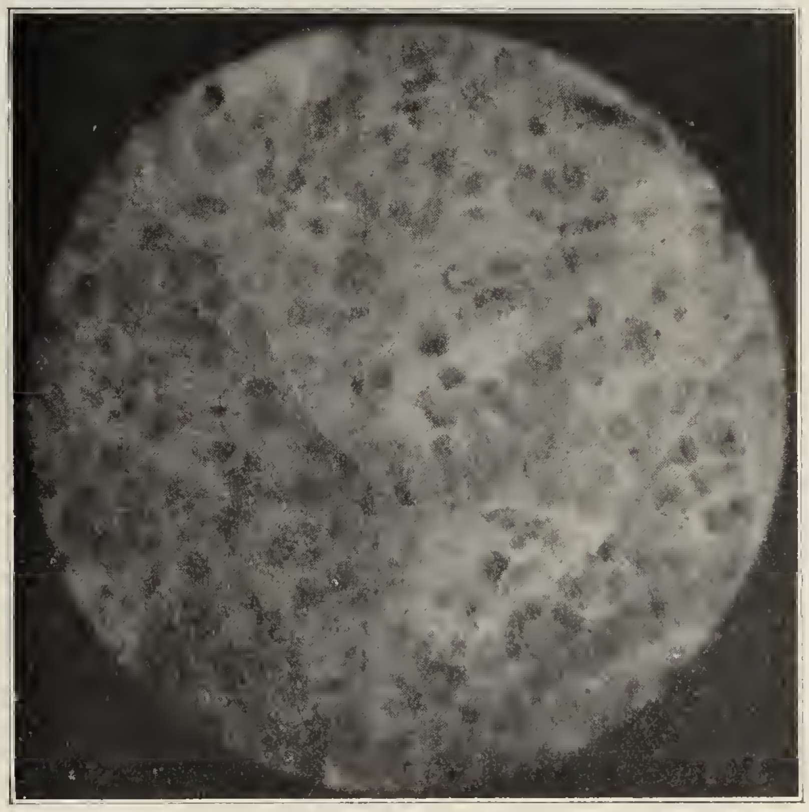

Fig. 9.—Squamous cell. Grade III, high power.

seem loosened and torn away. Vacuoles can be seen in the cytoplasm and fusion giant cells are present.

As this second stage progresses one will see liquefaction necrosis, reduction in the number of tumor cells, and a beginning invasion of lymphocytes and fibroblasts. In the third stage (Fig. 12) there are very important changes. The cells are practically all destroyed, or else so shrunken and encapsulated by fibrous connective tissue that they are inactive. Fragments of nuclei and giant cells remain, the former being actively removed by the phagocytic action of the exudated leucocytes. This stage progresses immediately into the fourth stage (Fig. 13), or stage of fibrosis. The areas of liquefaction necrosis have been replaced by fibrous tissue, and the strauma of the tumor is nothing more than granulation tissues rich in capillaries. The illustrations will show how the fibroblasts permeate the tumor cell nests and spread in all directions. This connective tissue breaks open the cell complexes, presses them together and strangulates them. The hemorrhages which take place very soon after radiation and which are caused by the destruction of the blood capillaries, are organized and replaced by the fibrous tissue.

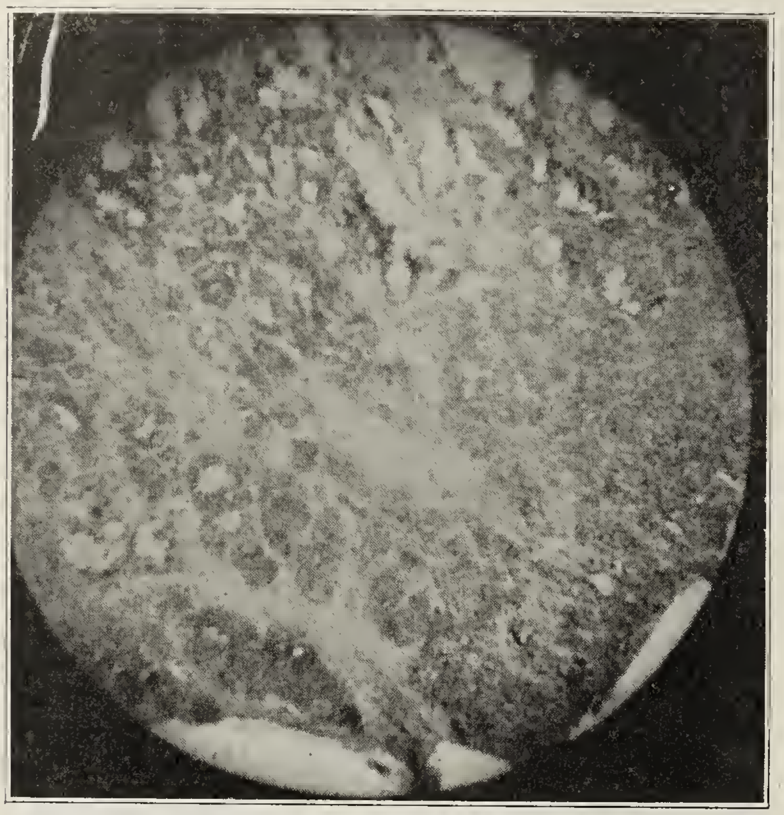

Fig. 10.—Squamous-cell. Grade IV, low power.

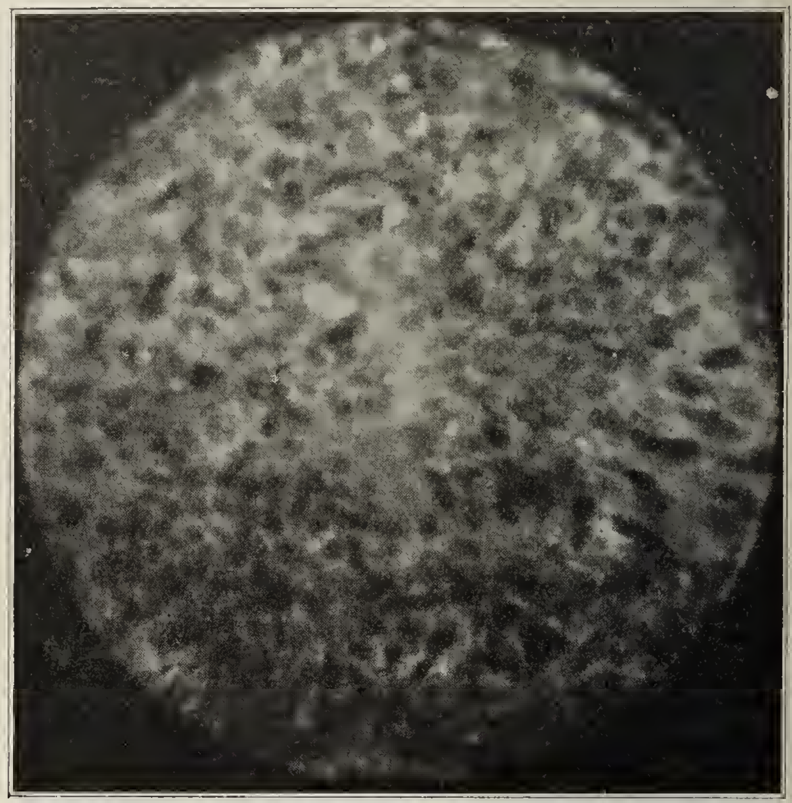

Fig. 11.—Squamous cell. Grade IV, high power.

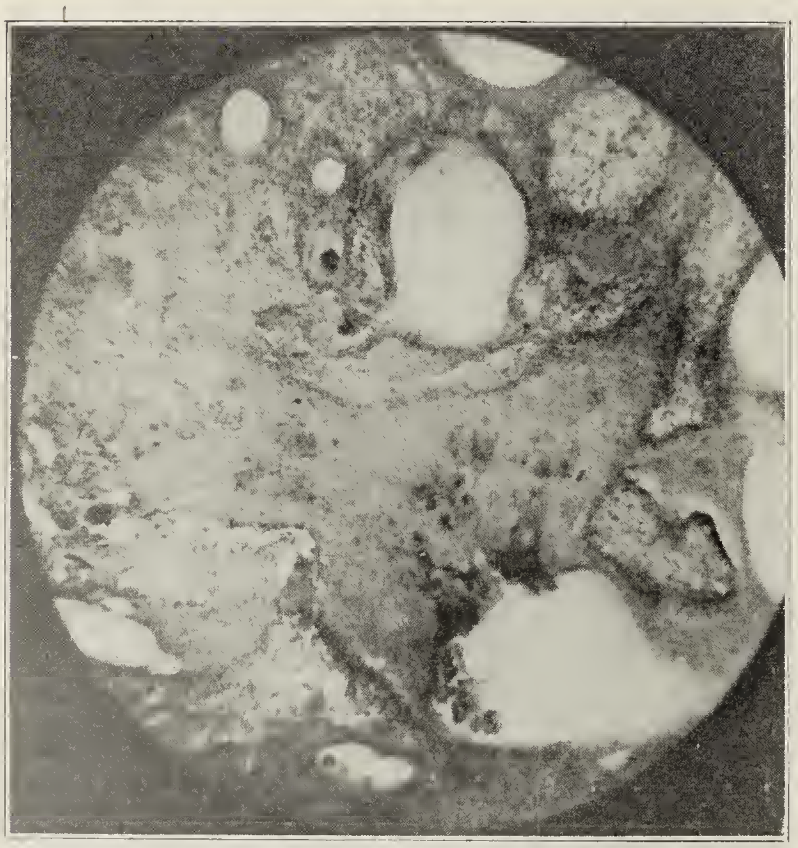

Fig. 12.—Squamous cell after radiation. Third stage.

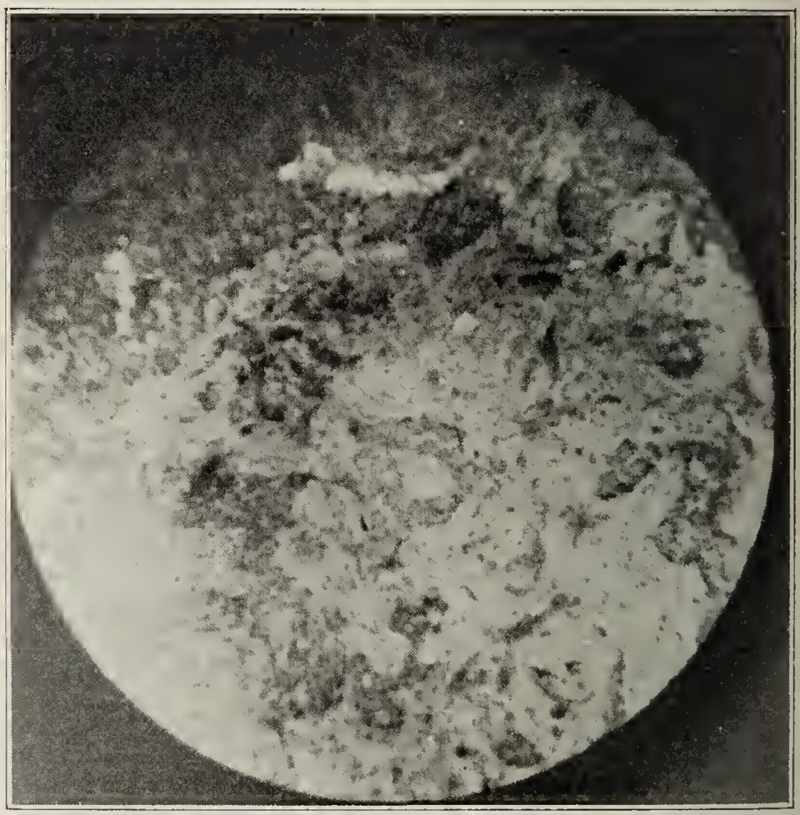

Fig. 13.—Squamous cell after radiation. Fourth stage, showing fibrosis.

Finally, this connective tissue shows signs of maturity, the cells diminish in number and only the scar remains.

Hypertrichosis and Its Treatment*

By LAWRENCE K. McCAFFERTY, M.D.,
New York.

Excessive growth of hair confined to the face is common in women. It is here that the physician may render a real service. Most women are sensitive about even a few hairs upon the face, but when there is a real overgrowth they may shun society, live secluded lives or even become melancholic. By careful treatment the worst cases may be cured, and the patient is returned to society with a healthy outlook upon life.

KINDS OF HYPERTRICHOSIS.

We have two main divisions of hypertrichosis—congenital and acquired. The congenital type may be partial or universal. The partial type of congenital hypertrichosis is best represented by the hairy mole. The universal congenital type is rare but does exist. The Russian dog faced boy was an example of this latter type. Unna (1) believes that at the time of birth the fine papillary hairs of the embryo continue to grow, producing either localized (Fig. 1) or universal congenital hypertrichosis.

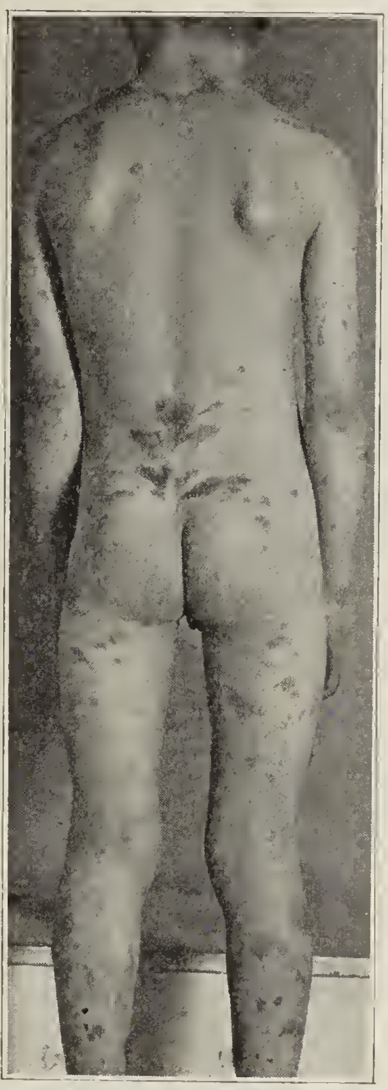

Fig. 1.—Localized congenital hypertrichosis.

ACQUIRED HYPERTRICHOSIS.

Acquired hypertrichosis is the type which interests us the more. It occurs in women usually between the ages of eighteen and thirty who have a noticeable amount of hair upon their faces. In women past the climacteric, one sees only a few scattered hairs or an occasional tuft. In young women Jackson (2) found the lip involved in twelve per cent.; the lip and chin in 38.5 per cent., and cheeks, chin and lip in thirty-four per cent. The hair in blondes at first is barely visible, while in brunettes it is pigmented and stands out sharply. The patients may use depilatory creams, tweezers or the razor. The hair is gradually changed from a fine, hardly noticeable lanugo to very thick, coarse hair similar to that of a man's beard.

ETIOLOGY.

The etiology of acquired hypertrichosis points to a disturbance of the endocrine system. Falta (3) states that a pathological process beginning in one gland will, to a greater or less degree, cause disease in all the others. The internal secretion of one gland reaches another through the circulation and there either increases or inhibits functional activity.

Draper (4) reported two cases with a pathological disturbance of one endocrine gland. The first patient presented in each kidney region a small hard tumor. She made a striking picture of virilism with secondary sex characteristics. Hair appeared on the face and body late in life. The condition was evidently due to tumors of the adrenal cortices. The second case reported by Draper (a case which I had the opportunity of seeing and studying) presented a mass in the pelvis connected with the uterus. She has had hair upon her face since her eighteenth year and it is still increasing. The male secondary sex characteristics are strongly developed, especially in the face. This is shown by her expression as well as the distribution and coarseness of the hair (Fig. 2). Draper thought this to be due to a tumor of the ovary. Alfred Callais (5) reports several cases of suprarenal tumors with marked secondary sex characteristics usual to the opposite sex. Progressive hypertrichosis in these women was one of the subjective symptoms which first brought the patient to a physician. Bechet (6) believes that hypertrichosis is the result of functional organic derangement of the ovaries.

Cushing (7) observed that during the period of activity of acromegaly hypertrichosis increased. He found that the adiposogenital syndrome occurred with derangement of other ductless glands than the hypophysis. He cites a case of a young woman aged nineteen who had a grown beard and moustache. At autopsy they found a malignant adenoma of the left suprarenal gland. Biedl (8) states that during pregnancy the influence of metabolism which is undergoing changes, as well as the modification of internal secretory glands, leads to manifestations such as increased hair growth. Pregnant rabbits show a striking growth of fur.

After physiological senile atrophy and pathological degeneration of the ovaries have taken place, often, but not always, a heterosexual change has been observed accompanied by the occasional development of a beard. Heredity, no doubt, plays a rôle in the development of hypertrichosis which, however, does not manifest itself until after puberty. It is no doubt true that the overgrowth of lanugo is possibly due to the disturbance of endocrines. However, with the exception of such cases as Draper's, hair which develops from coarse lanugo is undoubtedly due to mechanical irritation.

TYPES OF PATIENTS

The types of patients presenting themselves for treatment vary to a great extent. Briefly these may be grouped as follows:

The patient who has a very fine white lanugo on the upper lip and sides of the cheeks. The hair is noticeable only to herself and should not be removed unless it is affecting her personality. The second type is the brunette who has a short, fine black lanugo on the upper lip. This is natural for a dark complexioned person. It adds a certain artistic picture which is natural for that type of individual.

---

*From the dermatological service of Dr. H. H. Whitehouse at the New York Skin and Cancer Hospital.

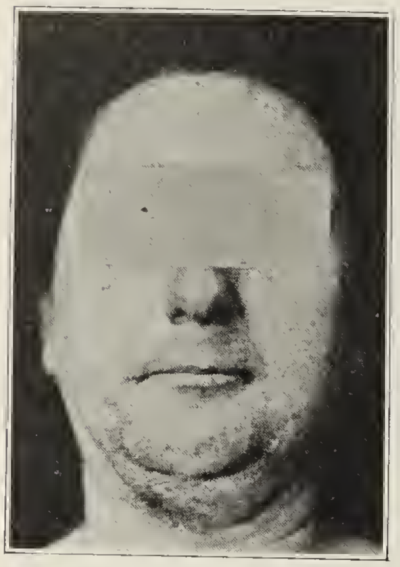

Fig. 2.—Secondary sex characteristics and hypertrichosis shown by the subject's expression as well as the coarseness and distribution of the hair.

The third type is the blonde who presents a very fine, long lanugo hair which has become pigmented at the ends. This usually occurs on the upper lip, especially above the commissures and on the chin following the rami of the inferior maxillary bone. This condition is an indication for electrolysis. The fourth type is the brunette presenting long fine black hairs appearing on the upper lip and chin. Electrolysis is here recommended. The fifth type is either blonde or brunette, usually the latter, presenting an excessive growth of hair on the sides of the face, the neck above the hyoid bone, the chin and sometimes the upper lip (Fig. 3). Much may be done by electrolysis for such a patient.

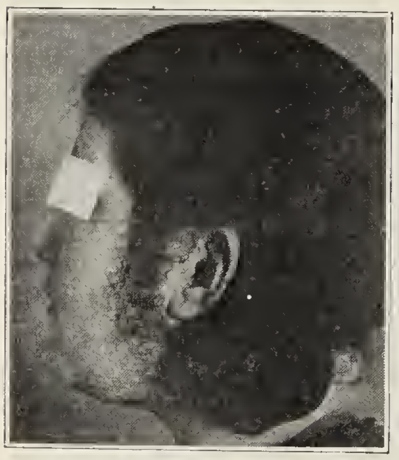

Fig. 3.—A type of hypertrichosis presenting an excessive growth of hair on the sides of the face, chin, and upper lip.

The sixth type is the patient who shows coarse, stiff, long hairs, either light or dark, depending upon the complexion of the individual. The hairs usually occupy the same regions as the male beard (Fig. 2). This type of hair is indicative of a heterosexual tendency, or that the individual has persistently extracted the hairs. It may be due to a combination of the two. This condition is a real indication for treatment. The seventh and last type represents those women during, or several years after, the menopause, who present either small tufts of hair in one or two places on the face (Fig. 4), or several long coarse hairs scattered over the face.

ELECTROLYSIS.

Giovanni (9) states that the changes produced in the single hair follicle as well as in the hair matrix and sheath of the hair are so great that electrolysis may be considered successful. The apparatus necessary is well known to all. It has been my practice, thanks to the instruction of Dr. George M. MacKee, to use a needle holder, etc., which will permit the needle to be placed at any angle. By using this holder, the hand may rest upon the face and prevent tremor of the fingers. The needle should be extremely fine and pointed. The electrode, which is the positive pole, may be about three inches square and is covered with wet absorbent cotton. The needle holder is attached to the negative pole. This should never be reversed. If it is, the current will cause a charring of the tissues and a black spot will remain permanently. T. C. Gilchrist (10) has found the use of a magnifying lens valuable in doing this work. Daylight is preferable for this work, but it may be done at night by the aid of a blue tungsten light.

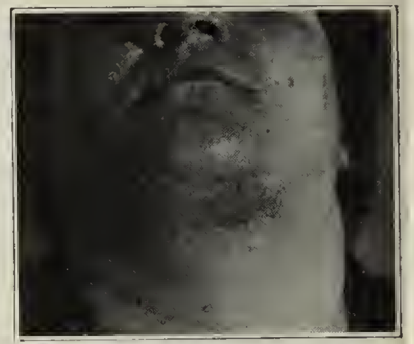

Fig. 4.—A type of hypertrichosis where the hairs are arranged in tufts.

There are a few things one should bear in mind in order to obtain the best results. As a general rule one half milliampere on the upper lip and on fine lanugo hair has been found best. For all other locations on the face when one is dealing with hair that is coarse and deeply imbedded in the subcutaneous tissue one milliampere is suggested. It was never necessary to go above this amount. It has been found advisable to equip oneself with a milliampere meter which may be placed near the operator's head. The distance between each milliampere should be about an inch. This will make it possible for the operator to read accurately from one tenth to one milliampere. One may use the same milliamperage each time upon the same patient, thereby obtaining uniform results.

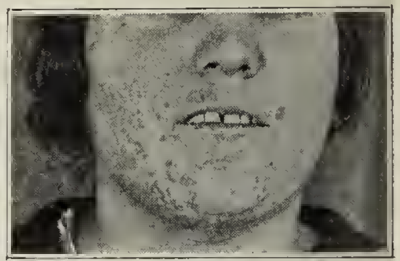

Fig. 5.—Sequelæ of x ray treatment for hypertrichosis.

The needle should be placed directly into the follicular mouth, following the hair follicle to a depth varying from one sixteenth to three sixteenths of an inch. If the needle does not enter the hair follicle it meets with resistance and a blanching of the skin occurs around it. If the needle is properly inserted, a white foam or froth exudes from the hair follicle. This is due to the liberation of hydrogen within the hair follicle. While the needle is still in place, the hair is removed with the slightest traction. When noticeable traction is necessary, it means that the hair bulb is not completely destroyed, in which case the operator should return to it in a few minutes and by the slightest traction it will slide out. The electrolytic action evidently continues for several seconds after the needle has been withdrawn.

A few minutes after the hair has been lifted from the follicle, a tiny brown halo appears, showing that destruction has occurred. Following this there appears a pin point sized umbilicated vesicle which is slightly yellow; later a slight edema or wheal appears. The above reactions are increased and hastened by increasing the milliamperage. In twenty-four hours a small crust forms over the umbilicated vesicle. A scab generally falls within a week, leaving a brownish red pigmented spot. The pigmentation fades completely in three to six weeks, leaving in some cases a barely noticeable white scar, whereas in other cases no visible trace is left.

NUMBER OF TREATMENTS REQUIRED

The number of treatments required for a patient with hypertrichosis varies with the amount and type of hair. Lanugo hair may be removed at the rate of one hair every thirty seconds, using one half of a milliampere. Coarse, stiff, deeply imbedded hairs will require one minute at one milliampere. Hairs from a mole require two minutes at one milliampere. Two or three weeks after the hairs have been removed from a mole, one will notice that the mole has partially disappeared. It is advisable to remove the remaining pigmentation. Care should be taken that the patient is not subject to keloidal formation for obviously a keloid will develop on the nevoid site. The hairs upon any location should not be removed too closely, otherwise the area will become edematous and indurated. When the induration has undergone involution, scarring or atrophy may remain.

A few hairs do return after electrolysis. This is due either to insufficient destruction of the hair papilla or to a curving of the hair root in the subcutaneous tissue. The curving root is found usually on the anterior neck. When all the coarse hair has been removed from a case such as Fig. 3, a fine lanugo may grow. Brocq (11) calls this a secondary growth. He states further that even a third growth may appear. This, however, is the exception rather than the rule.

HISTOLOGICAL CHANGES RESULTING FROM ELECTROLYSIS.

The histological changes have been worked out by Giovanni in a most exhaustive article. He found the effect of electrolysis extended far and near. The sebaceous and sweat glands nearby either undergo atrophy or are destroyed. The fat cells are pushed away from the hair follicle and degenerate, leaving cavities. The lanugo hairs in the neighborhood are destroyed. Scar tissue closes up the hair follicles by the ninth day while in the subcutaneous tissue around the hair papilla scar tissue continues to form until the fifty-eighth day. A slight pigmentation remains at the epilated hair follicle fifty-eight days later.

X RAY TREATMENT.

X ray treatment of hypertrichosis fortunately is relegated to the past. A few years ago several dermatologists who were skilled also in x ray therapy believed that they had finally found an agent which would permanently cure hypertrichosis, but after they had seen the end results of such treatment they gave it up in despair. It requires from one to one and one quarter skin units unfiltered (measured dosage of Remer and Witherbee) (12) to cause a defluvium upon the face. This dosage is the same as one or one and one quarter Holzknecht units at skin distance unfiltered. The hair will regrow in from one to three months unless one skin unit unfiltered or a slightly smaller dose is repeated. This dose should be repeated every six weeks for a total of from six to eight treatments before a permanent result is effected.

One skin unit unfiltered will almost always produce an erythema in blondes; repetition of such dosage is almost sure to produce sequelæ (Fig. 5), such as telangiectasia, atrophy, wrinkling, and pigmentation. Such sequelæ do not occur usually before one or two years and are permanent. The erythema from filtered radiation will produce the same sequelæ. Until such end results may be avoided, x ray should not be used in treating hypertrichosis.

RADIUM TREATMENT.

Radium has been used by Heidingsfeld (13), Speder (14), and others, but inasmuch as its action is similar to x rays, it will not be discussed.

DEPILATORIES.

Depilatories when continuously used may cause a chronic dermatitis, although some patients have used them for years with apparently good results. Their principal ingredient is barium sulphide. It may be mentioned here that cold creams especially those containing lanolin, are accused of stimulating lanugo hair. I cannot agree with this nor have I been able to find any reference to such an action in any of the literature that has been written on this subject.

CONCLUSION.

I wish to express my thanks to Dr. John A. Fordyce for permission to photograph and publish some of the cases that came under his service at the Vanderbilt Clinic; to Dr. George M. MacKee I am especially indebted for his many valuable suggestions and for the privilege of studying and photographing private patients, some of which are used in this article; to Dr. George Draper, for the privilege he extended me at the Presbyterian Hospital in studying one of his cases, as well as the use of the photograph, and to Dr. H. H. Whitehouse, for his kindness in allowing me to publish one of the photographs from his clinic.

Pruritus with Lichenification

Further Observations on Neurodermitis of Brocq or Lichen Chronicus Circumscriptus of Vidal

By FRED WISE, M.D.,
New York.

Numerical data pertaining to the occurrence of diseases classed under eczema in the local dermatological clinics present wide variations and gross discrepancies. The reason for this is not far to seek: an active and busy clinic will fall into the habit of conveniently classifying certain dermatoses under the caption of eczema, thereby swelling the eczema statistics to disproportionate dimensions. Among the affections giving rise to confusion the commonest are the industrial dermatoses, dermatitis venenata, dermatitis artefacta, the dermatophytoses, pompholyx and dysidrosis, and, lastly, the circumscribed and diffuse forms of pruritus with lichenification (neurodermitis of Brocq).

In the past five or six years the majority of these conditions have been more carefully distinguished and more properly classified; in fact, there are indications that the pendulum is beginning to swing in the opposite direction, for the dermatophytoses are by way of getting more than their just share of blame for many obscure types of dermatitis. But when it comes to Brocq's neurodermitis, which at least in New York is certainly a common disease, clinically resembling eczema, but in reality not eczema at all, we find that this entity is still subjected to the humiliation of being incontinently flung upon the eczema refuse heap by the majority of American dermatologists.

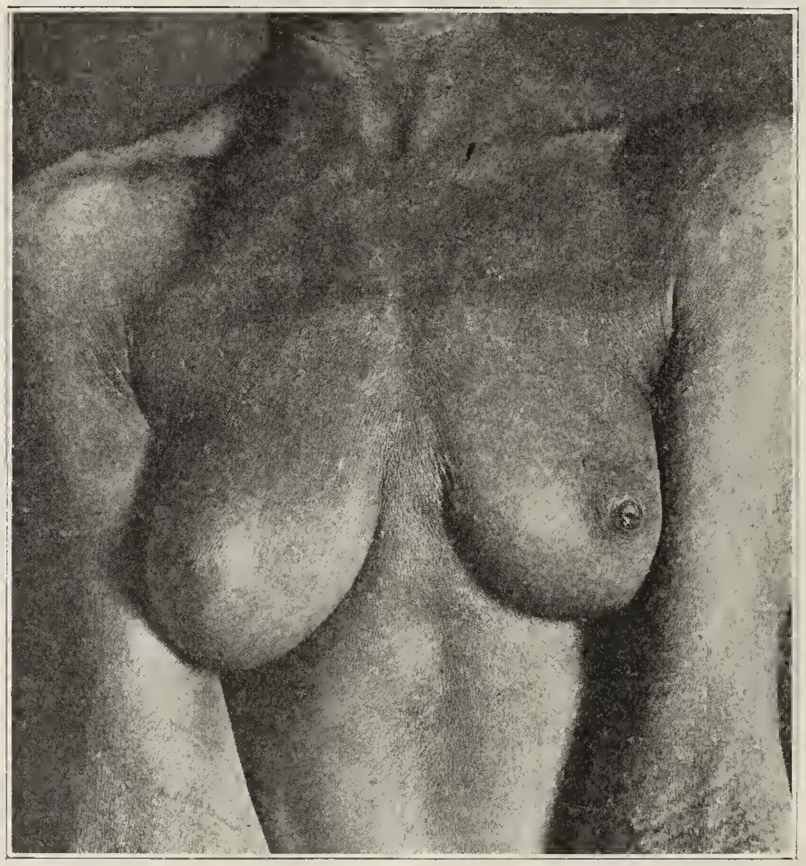

FIG. 5.—Neurodermitis, diffused type. Showing characteristic lichenification of entire cutaneous envelope. Private patient, a victim of chronic hayfever and asthma. (From author's article in *Jour. Cutan. Dis.*, September, 1919, p. 590.)

In his careful and elaborate work on pruritus with lichenification, Brocq (1), adequately covered the entire ground. As stated in a previous paper (2) on this subject, his writings in this particular field have not been sufficiently read and studied by his colleagues in other countries. Had they been more carefully perused and memorized, our statistics on eczema would have undergone many revisions. Vidal, Besnier, Brocq, Jacquet, Touton, Neisser, and many others after them have demonstrated that pruritus with lichenification, or neurodermitis, is not eczema, any more than it is lichen planus, despite the fact that it occasionally does resemble one or the other of the two latter diseases. It is a disease entity and requires no support to stand by itself. Clinically, syphilis often is indistinguishable from lupus vulgaris; psoriasis from seborrheic eczema; tuberculosis from blastomycosis; scarlet fever from a drug rash. The manifold resemblances to each other, of different forms of dermatoses, cannot be invoked as arguments in favor of any relationship between them. Eczema, lichen planus and neurodermitis are three separate and distinct dermatological entities.

In this connection, mention should be made of an article published by M. Dind (3), of Lausanne. This author reviews the relevant publications on the subject, including the clinical and histological features of the disease, and by various obscure and devious paths, he comes to the amazing conclusion that all forms of lichenification are practically identical with lichen planus, and belong, etiologically, to the infectious and parasitic group of skin diseases. Every man has a right to express his opinions and to publish them broadcast if he wants to, but one can safely surmise that had Dind permitted "his friend and master," Brocq, to read his paper prior to its publication, no such jumble of dermatological distortions would have graced the pages of the foremost French journal devoted to diseases of the skin.

Lichenification and lichen planus should never provoke confusion, even in the minds of beginners. Lichenification and eczema are often justifiably confused, even by the expert. The first two differ vastly in their mode of origin, in their incidence as to age of patients, in their areas of predilection on the body, in their gross clinical appearances, in their histological structure, in their course, sequelae and terminations; last, but not least, they differ in that lichen planus attacks the mucous membranes, while pruritus with lichenification does not, Dind to the contrary notwithstanding.

Primary lichenification may well be the first clinical evidence of leukemia and pseudoleukemia (see Fig. 1), mycosis fungoides and other dermatoses having not the remotest relation to lichen planus. Secondary lichenification may supervene in almost any affection associated with severe itching and scratching, as it often does in pruritus cu-

taneus, scabies, pediculosis, eczema and dermatitis, and even in lichen planus itself. The resemblance between lichenification and lichen planus lies in their names only.

In the article previously mentioned (2) I submitted a free translation of Brocq's work on pruritus with lichenification, in the hope that a perusal of it would tend to induce the reader properly to classify the affection, if only for the sake of rectifying existing errors as to figures bearing on the incidence of eczema.

Briefly recapitulated, the salient features of pruritus with lichenification are as follows: There are two main varieties, the primary and secondary. The eruption may be circumscribed or diffused; it may attack an area as small as a silver half dollar and remain restricted for months or even years to such a small patch, or it may involve almost the entire skin. Such circumscribed and diffused examples are described and illustrated in the preceding article (2). The primary variety results from protracted scratching and rubbing of an area of skin which is pruritic, but which, in the beginning, presents no visible lesions. The itching may precede the visible changes in the skin for months. This continued trauma, acting in conjunction with other factors residing within the affected individual, such as hay fever, asthma, bronchitis, gastrointestinal disturbances, perhaps excessive indulgence in tea, coffee and alcohol, and possibly certain obscure anaphylactic and endocrinous phenomena, results in a patch of neurodermitis. A goodly proportion of patients with neurodermitis present evidences of an unstable nervous system: irritability, excitability and neurasthenia are not infrequent concomitants. In children ranging from four to sixteen years, we see the patches most often in the cubital and popliteal spaces; in adults, more often on the nape and sides of the neck, the extensor surfaces of the knees and elbows, and the perigenital regions. No part of the cutaneous surface is exempt, however.

There is a peculiar and interesting clinical form of the primary variety of which I have encountered only three examples, all in children. The eruption is limited to the lower portion of the buttocks, the gluteofemoral fold and the upper posterior aspect of the thigh. The first case of this kind of which I have any knowledge was presented about five or six years ago, before the dermatological section of the

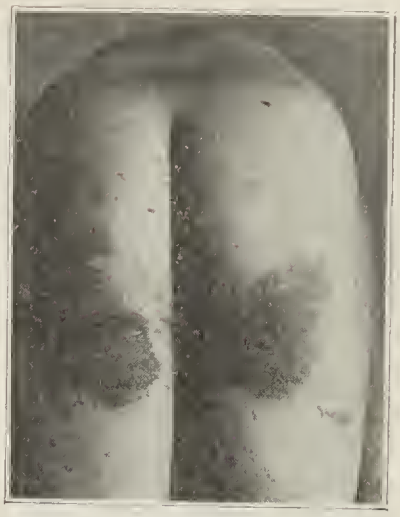

Fig. 2.—Pruritus with lichenification (neurodermitis). S. G., boy, aged 6. Private patient. An unusual localization, not due to external irritation, or contact with irritants on chair or toilet seat. Patches are papular and lichenified, never moist like eczema.

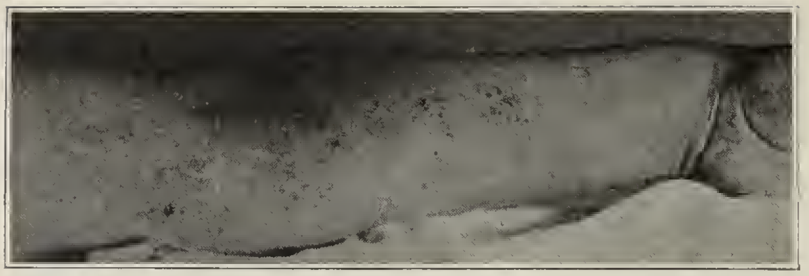

Fig. 14.—Neurodermitis, secondary variety, associated with eczematisation of the skin. Commonly diagnosed eczema. Adult forearm. (From author's article in *Jour. Cutan. Dis.*, September, 1919, p. 590.)

Fig. 12.—Neurodermitis, localized. Cubital area of child, a common area of predilection in children. Note crosshatching of skin, and crust formation from scratching.

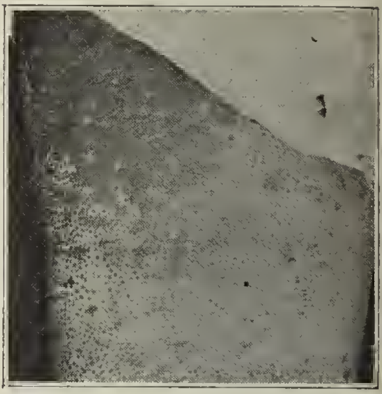

Fig. 13.—Secondary lichenification, following and accompanying eruption of pityriasis ruba pilaris. Inner surface of thigh of adult female, showing typical crosshatching of skin.

New York Academy of Medicine. The patient was a girl aged about five, who presented a sharply defined area of lichenification in the regions above mentioned. The inference was naturally drawn by the members of the section that the eruption was due to some form of irritant coming in contact with the skin, from the seat of the toilet; but careful questioning of the child's parents failed to substantiate this as an etiological factor; when the child was seated it was seen that the margins of the patches did not correspond to the outlines of a toilet seat and that portions of the skin were affected which would not come in contact with a toilet seat or with an ordinary chair. A similar case is at present under my care, in a girl aged fifteen, whom I have had under observation for five years. She is of neurotic habitus, and has neurotic parents. About twice a year, in the past six or seven years, patches of lichenification appear on the lower gluteal and upper femoral regions, without ascertainable external or internal factors to account for them. They are associated with considerable itching. Röntgen ray treatment is only of temporary benefit; the skin will clear up, the itching will stop for several months; then the child again begins to scratch, and a new outbreak occurs, located in almost exactly the same areas as before. The attacks are growing less severe as the child grows older. The third case (see Fig. 2) was observed in private practice, in a boy aged six.

MODE OF PRODUCTION OF CUTANEOUS LESIONS.

(From Brocq.) "At the outset there is absolutely no visible lesion on the part of the integument; gradually the tissues change as the result of scratching; they first lose their normal color and assume a slightly dusky and at the same time, pinkish tint. On close inspection the skin is seen to present a finely granular and mottled appearance. At this stage it is already possible to discern in certain localities, under varying illumination, a sort of flattened, poorly outlined, somewhat glistening, very minute pseudopapule formation. Later on, these lesions become more pronounced, the tissues assuming a dusky red color, or becoming distinctly pigmented; they are roughened or begin to be furrowed by fine criss-cross lines. The dermis gradually thickens, becomes infiltrated and the disease finally assumes a truly pathognomonic appearance.

"Having reached its stationary stage, circumscribed pruritus with lichenification has the general form of a more or less extensive patch of variable dimensions, but having an average diameter of five to fifteen cm. in its greatest axis. Its outline is extremely variable according to the case and the affected region. Although usually of oval shape, it may also be crescentic, semicircular, or irregularly triangular. It may develop on any part of the body surface. These patches may be single in a given subject and always remain single; they may be multiple; very often they are two or three in number. Sometimes they are symmetrical, especially when situated in the flexures. When a patch has reached a quiescent stage, it sometimes presents three somewhat ill defined zones: a somewhat diffuse, pigmented external zone; velvety, or as if composed of fine, very minute papules, varying from light café au lait to light brown color; a middle, papular zone with lesions which are scattered toward the external boundary and confluent toward the internal boundary, being apparently formed by a much more pronounced papillary hypertrophy than that which characterizes the preceding zone; and, thirdly, an internal infiltration zone of more or less uniform appearance, in which area the tissues are hardened, thickened and furrowed by a *rectangular or lozenge-shaped criss-cross design.* (Fig. 3)"

It is chiefly this cross hatching, this formation of pseudopapules, which distinguishes the affection clinically from lichen planus, with its independent, true papules, and from all forms of eczema.

In secondary pruritus with lichenification we have practically the same conditions to deal with, with this important exception: instead of the patch being preceded by pruritus affecting an apparently normal skin, the lichenification is superimposed upon an already diseased skin which itches and which the patient consistently scratches: scabies, eczema, lichen planus. The patient simply presents two different conditions, the lichenification having been superimposed upon the original pruritic dermatosis. As time goes on, the original trouble may even become obliterated by the lichenification, as I have observed in several patients suffering from true lichen planus; these are the rare instances, previously mentioned, in which the differential diagnosis between lichen planus and lichenification might be beset with difficulties. In chronic eczema, lichenification frequently takes place and then the condition is often designated lichenified eczema; the name makes little difference, but in reality it is lichenification in eczema. The same applies to any other pruritis, scratching disease like scabies or pediculosis (Fig. 4). In clinics with large services, hardly a day passes without the incidence of two or three examples of eruptions in which eczema and lichenification exist at the same time, and as the eczematous part of the eruption usually predominates, such cases are almost without exception classed simply under eczema.

In the diffused form of pruritus with lichenification, the appearance of the skin is practically identical with that of the circumscribed variety. The skin is at first dusky red, then becomes brownish and somewhat muddy-looking in color. The peculiar cross hatching may implicate the whole cutaneous surface, or large parts of it. The zoniform arrangement above mentioned and the formation of scattered papules are usually not present in this variety. Traumatic alopecia is a frequent concomitant. Dryness of the affected skin is characteristic, in contradistinction to eczema, which in its earlier stages is a moist disease (Fig. 5). This is a photograph of a young woman with universal lichenification, who for many years had been a victim of asthma and hay fever.

HISTOPATHOLOGY.

The microscopic structure of pruritus with lichenification has been described by Brocq and Jacquet, Darier, Dalous, Marcuse, Tommasoli, Kreibich, Fabry, Vignolo-Lutati, and others (4). More recently, Highman (5) studied a series of slides derived from patients in the dermatological department of the Vanderbilt Clinic; he pointed out the characteristic structural changes, and showed wherein these changes differed from those seen in eczema; among the latter he itemizes: 1, absence of vesicles in the epidermis; 2, absence of marked hyperkeratinization or marked parakeratosis; 3, absence of excessive fat in the epidermis, vessels, skin glands, and so forth; 4, absence of follicular involvement; 5, absence of disturbance of the pilosebaceous or sweat organs.

According to the recently conducted investigations of Arthur Alexander (6), there are three outstanding points in which eczema and pruritus with lichenification differ from each other: 1. In neurodermitis, despite the high grade of edema in the cutis and the epithelium, the stage of vesicle formation is absent, while it constitutes the prominent feature of eczema; in the farthest stage or development of neurodermitis, there may occur a sort of abortive, tiny vesicle formation (network structure), characterized by the formation of sharply circumscribed cell groups; in these, the protoplasm of the rete cells exhibits an intracellular, and a less pronounced intercellular edema, so that a sort of honeycomb appearance is manifested, in the meshes of which are seen wandering cells, fibrinous exudate, and the nuclei of epithelial cells. This network structure shows no tendency toward progressive or regressive alterations. 2. Neurodermitis is characterized, in its papular stage, by a wellmarked displacement or washing away of the pigment of the basal cylindrical celled layer, associated with a certain hyperpigmentation of the epithelium, in the less affected surrounding areas. 3. In neurodermitis there is an invasion of the epithelium of wandering leucocytes emanating from the papillary and subpapillary infiltration, so that the epithelial layer is studded with wandering cells; this invasion of leucocytes is sometimes so pronounced that it gives rise to a breaking up of the interpapillary prolongations of the cutis.

The question whether these three criteria are sufficient to designate neurodermitis as an anatomical entity is left open by Alexander; but he contends that clinically, the disease is an entity, to be sharply differentiated from other dermatoses.

The latest work on the subject is that of Bukovsky (7). He takes pains to express himself as being strongly opposed to the views submitted by Dind (3), and then goes into the details of his own clinical and histological investigations. The gist of his paper is about as follows:

Neurodermitis is a welldefined disease, *sui generis*, to be sharply differentiated from eczema, from lichen planus and from all other dermatoses. The actual macroscopic (visible) changes in the skin may be preceded for a long time, even years, by persistent pruritus. The primary lesion is a rounded, slightly elevated, glazed, smooth, reddish-brown papule, either isolated or occurring in groups, or forming confluent plaques of varying size. There are certain areas of predilection, such as legs, forearms, nape of neck, genital and anal regions.

Based on the mode of grouping of the lesions and on the course of the eruption, the author differentiates three clinical varieties: lichen simplex chronicus circumscriptus of Vidal; pruritus with lichenification; neurodermitis nodularis. The histological changes are identical in these three varieties. There is a papillary and subpapillary edema, sometimes extending into the deepest layers of the epidermis; dilatation of the bloodvessels; a proliferating inflammatory reaction, sharply defined, in the papillary bodies; a perivascular infiltrate in the deeper layers of the corium; a sclerosing of the connective tissue, extending downward from the papillæ; a complete absence of the elastic tissue in the sharply defined nodular infiltrates. The epidermis presents a moderate degree of acanthosis, but no evidences of inflammatory reaction.

Bukovsky believes that even before the appearance of macroscopic lesions on the skin, a toxic substance in the blood acts upon the peripheral nerve-terminals, causing the pruritus, the dilatation of the vascular elements, and the edema; in his opinion, neurodermitis is a condition arising from internal disturbances.

Lastly, my own observations, based on the study of numerous examples of eczema, lichen planus, and neurodermitis, and supported by the examination of microscopic sections, from which comparisons and deductions can be made scientifically, have tended strongly to confirm the views expressed in the foregoing, namely: 1, neurodermitis is a disease *sui generis;* 2, it possesses peculiar clinical and histological characteristics; 3, it is confused with eczema and occasionally with lichen planus; 4, it should be classed under a separate heading.

TREATMENT.

The treatment must be directed toward constitutional disturbances and toward the eruption itself. As stated, a certain proportion of patients are apparently in good health, while others are afflicted with various forms of so-called nervousness, insomnia, irritability, and so forth. My personal observations have demonstrated the fact that a goodly proportion of these patients have asthma, hay fever or bronchitis; some patients who are apparently otherwise in good health, give histories of respiratory diseases in the parents. Ehrmann (8) believes the dermatosis to be due to gastrointestinal disturbances and faulty endocrinous metabolism. He thinks that a relationship exists between faulty action of the pancreas and certain forms of neurodermitis. He differentiates two groups: The first embraces cases associated with gastrointestinal troubles or motor and secretory nature (anacidity, hyperacidity, faulty pancreatic digestion, atony of the stomach, intestinal catarrh, and so forth). The second group embraces the cases associated with disturbances of internal secretions.

The only internal remedy which I have found useful in a certain proportion of patients, is arsenic, given preferably by subcutaneous injection. Occasionally, aspirin may be found beneficial, to aid in the relief of itching. Patients with hyperthyroidism, seen chiefly in young girls, must of course receive adequate treatment for their constitutional as well as their cutaneous troubles.

The local therapy may be divided into medicinal local treatment; quartz light and x ray treatment.

The first thing to do is to direct one's efforts toward the cessation of itching; when the patient stops scratching, the disease tends to heal spontaneously. One of the best remedies is the following:

Calaminæ præp.	ounce 1
Pulv. zinci oxidi	ounces one and a half
Liq. carbonic deterg.	ounces 2
Phenolis	drams 2
Mentholis	grains 5
Glycerini	drams 2
Aquæ calcis	ounces 3
Aquæ rosea q. s. ad	ounces 8

Shake well. To be painted on with a camel hair brush, every three or four hours.

When the itching has abated and the inflammatory symptoms show a tendency to subside, the use of the lotion may be stopped and this ointment is applied:

℞

Naftalan	dram one
Phenol	dram one half
Menthol	grains three
Lanolin	ounce one
Vaselin, āā ad	

M. and f. ungt. S. Apply by gentle massage, morning and night.

These remedies will do well for mild cases, in which there is not a great amount of infiltration. In thickened and sclerotic patches, the best remedy is:

℞

Chrysarobin	grains ten
Phenol	dram one half
Menthol	grains three
Ungt. zinci oxidi., ad	ounce one

M. and f. ungt. S. Rub in gently morning and evening, using a rubber finger cot. *Caution.* Avoid contact of salve with eyelids.

It is advisable to place bandages over areas treated with chrysarobin ointment, to prevent accidental contact of the remedy with eyes. In cases associated with considerable scaling, salicylic acid in four per cent. strength should be added to this ointment.

In a certain proportion of patients, the local treatment as above outlined renders only temporary and shortlived relief. In these, the calamine compound lotion may be safely resumed for the immediate relief of the itching, and quartz light therapy may be instituted. An erythema dose, a sharp inflammatory reaction, should be administered at intervals of seven to ten days. The light is applied after the skin has been cleansed with a little oil or cold cream, then washed with dilute alcohol. The light often helps when medicinal remedies fail.

The best and most lasting benefits are obtained from x ray therapy. If strong preparations of tar, chrysarobin, mercury, sulphur, iodine, and so forth, have recently been applied to the areas to be treated, the x ray treatment must be held in abeyance until all evidences of a medicinal dermatitis have vanished —anywhere from two to four weeks. In the meantime, a half strength calamine compound lotion may be employed with benefit. The superimposed dermatitis having subsided, the x rays are applied either in one quarter Holzknecht unit doses, unfiltered, once a week, or in one half unit doses once in two weeks, these doses being computed at skin distance (9).

Although x ray treatment is indisputably the most efficacious remedy, it does not always, unfortunately, prevent recurrences in certain obstinate cases, although it probably induces longer periods of relief than the other remedies at our disposal.

For the accompanying illustrations I beg to acknowledge my thanks to the Dermatological Department of the Vanderbilt Clinic.

Historical Medicine

The Influence of Disease on History

By A. A. MOLL, M.A.,
Chicago.

The tragic death of President Harding, stricken as his predecessor, while pleading for more active intervention by this country in international affairs, only serves to emphasize once more by what a slight thread hang such vast human ventures as a nation's policy, the outcome of a war and even the world's future. The most learned, although by no means the most entertaining, of Gibbon's successors liked to dwell on the fact that no less than twenty-five times had the course of history been diverted in the nineteenth century by actual or attempted crime. Morley, who prided himself on his knowledge of famous events, apparently considered this number far too large. And yet, it should not have been too hard for Rousseau's biographer to recall that somber list written with dagger, gun, and bomb in his own times: Kleber (1); Paul I (2); Cadoudal (3); Staps (4); Kara George (5); Kotzebue (6); Duke of Berry (7); Sucre (8); Miloradov (9); Constantinople bishops (10); Capo d'Istria (11); Fieschi (12); Rossi (13); Orsini (14); Richardson (15); Lincoln (16); Berezowski (17); Pierre Noir (18); Prim (19); Nobiling (20); Abdul Azis (21); Alexander II (22); Phenix Park (23); Garfield (24); Stambuloff (25); Czarevitch (26); Carnot (27); Cánovas (28); German missionaries (29). This does not take into consideration murders such as those of Ali Pasha; attempts on women rulers (Victoria, Isabel, Elizabeth); Latin American executions (Monteverde, Garcia Moreno, Heureaux); legalized murders (Enghein, Toussaint-Louverture, Hofer, Palm, Ney, Maximilian, Rizal); plots and revolts (the one against Alexander is said to have shortened his life); massacres (May 2, Chio, December 11, Armenia); duels (Hamilton-Burr, Carrel-Girardin, Montpensier-Bourbon), self-murders (Castlereagh, Boulanger, Balmaceda, Archduke Rudolph), and leaves practically untouched the fertile Eastern field. While the historical importance of these crimes may vary, who can deny their bearing on human evolution?

For those who saw the start of the World War, there is no question as to the curious twists given by assassination to history. In fact, advocates of its usefulness have never lacked through the centuries. The greatest of Latin philosophers did not hesitate to add a few sentences to his treatise on old age (or was it the one on friendship?) to justify and doing away of his patron, Cæsar, and a famous priest, Father Mariana, was not at loss for reasons to excuse regicide. Talleyrand cynically could not understand such a despotism as Russia's, unless tempered by murder.

But deep as are the effects of crime there is another factor just as powerful, but more neglected —disease. American Presidents have been struck down even more times by physical ailments than by murder. We may just cast a passing glance at the deepseated, protracted consequences visited on a whole nation by endemics, such as ankylostomiasis on China and Egypt, and malaria on "the glory that was Greece and the grandeur that was Rome." Though more continuous, its effects are fairly similar to the murder on a large scale, called war. We may also overlook the pestilences which drove whole nations to seek a new home elsewhere, such as took to Italy, the Etruscans, the old masters and rivals of Rome, and probably lurked behind the first onrushes of the Barbarians which finally crumbled into dust the Cæsars's vast empire.

Epidemics which affect contending armies nearly the same can hardly be deemed factors in the outcome. Even in the 1812 campaign, that bugaboo so often used by sanitarians, the Russians lost nearly as many men as the French from disease, at least in the early stages. (The Czar's own brother in law died from typhus fever.) There is no use either in turning to such outbreaks as spared neither friend nor foe. The evenness of the punishment impeded the tilting of the scales. The Trojan War was thus prolonged through the epidemics in both camps. Rome was also ravaged in practically every decade of its stormy existence. In one of these periodical scourges, the Sybilline books advised bringing from Epidaurus the serpent, symbol of Æsculapius. In other cases, however, we may see a battle, a campaign, and even a war or a nation's fate, decided by one of those tidal waves of sickness, called epidemics. One of the causes to which the Romans attributed their decay was the fact that diseases propagated more easily in the climate of sunny Italy than amidst the ice and snow of the North, whence the numberless Barbarian hordes emerged. We all know that a plague was chosen by God Himself as one of His instruments to afflict the Pharaoh into releasing the Chosen People. It is true that they had not been long out of Egypt when their indulgence caused another visitation which carried off not less than twenty-four thousand of Moses's followers. Let us turn instead to more dramatic instances.

In the most critical hour of the French Revolution, there is one man alone who seems strong enough to bar the angry waves of revolution and anarchy. Yet that man, Mirabeau, still in the prime of life, is snatched off just when most needed, by diaphragmatitis, or perhaps by too much enjoyment of life. Italy, said Gladstone, might have been different, had not a premature death claimed Cavour and Ricasoli at the hour of her greatest need. Had Henry V not gone to an early grave the crowns of France and England would in all likelihood united on his head and the War of the Roses died unborn. How strange would American history perhaps read, had gout not darkened Chatham's mind and thus destroyed his influence in

George III's councils! How diverse would events have turned should any physician been able to find a specific to cure Timur's game leg; Juana and Charles VI's voluptuousness; Mary Stuart, Isobel and Maria Luisa's flightiness, Charles V and Philip II's gout. Take feeblemindedness off Charles II and the bloody Spanish Succession War would never have broken out. In fact, the same end might have been attained by preventing the disease which snatched away the Electoral Prince of Bavaria's infant son. Had not James II died at that very moment, England would have kept out of the war and Austria, unsupported, would have also remained quiet. And finally, had not the Austrian Emperor died and his brother Charles ascended the throne, the conflict would undoubtedly have lasted longer.

What a different world this might have been if consumption had not snatched the elder brother of the last Russian Czar; cancer not killed prematurely the father of the last German Kaiser, and death not claimed before their allotted time the father and the elder brother of the present British King. Former Prime Minister Asquith has not hesitated to place on record his conviction that the unexpected death (appendicitis) of Baron Marschall von Bieberstein was an international calamity, as, had he lived, the World War probably would not have taken place. Historians may do worse than dwell upon those paralytic attacks which, after disabling an American President at a tragic hour for mankind, shortly afterwards crippled the greatest Russian ruler since Peter I. Another man would now be at the White House had not a thrombus put a sudden quietus on Roosevelt's intense life.

Josephine's barrenness drove Napoleon into the arms of an Austrian Archduchess, as he said himself, to blind him to his danger. Had there been a way to cure Henry IV's impotence, the greatest of Spanish rulers, the Catholic Kings would never have ascended the throne, and Columbus might never have found a sovereign to send him on his quest of a new world. Discard Loyola's lameness and the great company which fought Protestantism to a standstill would never have come into being and the Reformation might have swept on beyond the Pyrenees and the Alps.

Probably the most dramatic events in 1922 were Lloyd George's downfall and the sudden recovery of Turkey. All this can be traced to an attack of rabies caused by a mad monkey. After having increased practically threefold the size of his country, Venizelos, the greatest Greek statesman since Pericles's days, was suddenly thrown out of power when his master, Alexander, was bitten by his pet and finally died. Constantine, recalled to power, courting popularity and English favor, embarked on his costly Eastern adventure. The Turk turned and the Greek defeat was followed by the ousting of Constantine. Then Lloyd George, who had backed Hellenic ambition, was forced to show his hand. The Turk would not be bluffed, England was averse to fighting, and the last survivor of the "Big Four" went down ignominiously.

Go back to one of the most meaning hours for humanity. Greece, united, had saved the world for Hellenism. But in the hour of victory the forces broke apart and the two great Greek states, embodying opposite ideals, Athens and Sparta, clashed. Athens, headed by one of the greatest statesmen of all times, Pericles, seemed likely to come atop. Then the plague, so masterfully described by Thucydides and Plutarch, entered the lists. More than half the Athenians died, including the illustrious chief himself. Sparta conquered. The Athenian, from a doer in the field and on the waves, became a thinker. No more Parthenons were built, no more Salamis were won, but Plato lectured at the Academy and Aristotle taught at the Paripatos.

Alexander, the nearest approach to a demigod this earth of ours has ever seen, while looking about for new worlds to conquer, was perfecting his idea of blending two civilizations, East and West, the twins of Father Time. His genius, the wild impulses of youth subdued, seemed to promise mellow years of peaceful progress. Yet at that very moment, the swordsman of Greek culture was stricken with a fever bred in the marshes of Babylon. Philip's son died in old Hammurabi's place, when he was thirty-three years old. His generals, as the bard put it, mere subjects with Alexander alive, but kings with Alexander dead, fought for his legacy, and the Macedonian's dream of a united world was drowned in tears and blood.

Rome faces her greatest danger. Hannibal, after destroying her armies, is knocking at the doors. Yet there is Capua on the way and the insidious fevers of the Roman Campagna. When the time comes again to strike, the Carthaginian host, ravaged by malaria, are unequal to the task. A few centuries afterwards, the mistress of the world is once more threatened. Attila is headed towards the Tiber. As the blow is about to fall, a hemorrhage carries off the Barbarian on his wedding night, and Romulus's town is saved. Mohammed's genius has reached its meridian. From his far Arabian corner, militant apostles are sent afield, Koran in one hand and sword in the other. Vast plans are forming in his agile mind when a malignant fever rushes the Prophet away in ten days to his paradise. The Normans were able to secure a hold in France because the last of the Carlovingians, Charles the Fat, was an epileptic, unfit for active work, who wanted to be left alone to the exquisite torture of his migraine.

Let us recall one of the world's epochmaking crises. Pope and Emperor were engaged in their death tussle as to whether the sword or the miter shall prevail. One of the most powerful of German sovereigns decided to make short shrift of the question. Barbarossa collected an army, crossed the Alps and stormed Rome. In the hot Italian summer, sunstroke and typhoid decimated his troops—his losses in one week were placed at twenty-five thousand—and he failed ignominiously. Ten years later, when he decided to retrieve his luck, it was too late. The start of the quarrel between the ablest of his successors and the Papacy may be traced to Frederick II's sudden illness just before his departure for the Holy Land. Gregory IX claimed that the indisposition was feigned by the

Emperor so as not to lead the crusade. Towards the last of the moving drama, dysentery gave the victory to the Holy Father by snatching Frederick while still in the field. The popes, at the last, were able to get the supremacy only through the untimely death of Henry III in Hildebrand's time and Henry VI in Innocence III's. The Crusades, by the way, failed as much through the frightful losses caused by epidemics as through the dissensions of the Crusaders themselves, and their last great leader, St. Louis, died from dysentery in Tunis. When Robert Guiscard was planning to substitute a martial Norman dynasty for the effeminate Constantinople rulers, an epidemic blasted his hopes in the island of Cephalonia, as another epidemic had blasted them a few years before, in front of Durazzo.

In 1494 Charles VIII conquered Naples, landing what looked like a body blow in the century old rivalry between France and Spain for Italy. But a new enemy had just put on his gaudy armor. About this time, a Genoese adventurer had plunged through unknown seas and, in the poet's words, "pulled a new world out of the deep." With it, however, another novelty had also come, syphilis. Quite unwistfully, the Spaniards had taken this ally into Naples. The disease proved the French's worst foe. Not a year had elapsed from Charles's triumphal arrival when he was back, as a fugitive, at the Alps. Hard as the French kings tried afterwards, Italy remained a Spanish possession for over two centuries.

One of the masterpieces of politics and literature, in fact, the mirror of an age, is Machiavelli's *Prince.* Its prototype had been one of the mot unscrupulous and capable politicians of the times, Cesare Borgia. With all his talents, he failed, in sight of the goal, because of an ill timed complaint. For years, Cesare had been laying quietly his plans to drive the foreigners from Italy, and build himself a kingdom. All, however, pivoted on the support of the Holy See. Cesare had therefore made elaborate arrangements to elect a pope of his own choice when his father died. At Alexander's death, it so happened that the son had just been taken sick with dysentery—poison, said some—and the helpless invalid had to strike a poor bargain with his worst enemy, Cardinal della Rovere, presently Julius II.

Do you want to know when and how the problem of Alsace-Lorraine, which ultimately was to flood Europe with blood, really started? The three famous bishoprics, Metz, Toul and Verdun, had always belonged to the German Empire. About 1552, when Charles V was looking in another direction, Henry II took possession of the three. The Emperor tried to regain his own and besieged Metz, the maiden stronghold. One of the bravest of French generals, Guise, threw himself into the fortress and took charge of the defense. Charles might have succeeded, but for typhoid thinning his ranks. At last, he gave up, uttering his famous words as to fortune being alike to a beautiful wench, fond of youth and turning her back on the aged. His failure began a never ending conflict between two proud nations. The siege was memorable in another respect. Charles had no surgeons with him, but Guise had been wiser. Inside the town was the greatest surgeon of his epoch, Ambroise Paré, and the magnanimous chieftain advised him to care for the soldiers left behind by Charles. This was probably the first instance on record—if we except Saladin—of such a generosity towards an adversary. Yet the Red Cross was still four centuries away.

References have never lacked to the Black Death of the fourteenth century, the "terrible plague like fire" of Bocaccio's narrative, which swept the Old World from one end to another. Petrarch thought posterity would be loath to believe there was once a time when the globe was nearly unpeopled, the homes without families, the towns without citizens and the countryside without farmers. Europe and Asia lost probably twenty-five millions apiece, about one half of their population. This visitation really planted the seeds of the Reformation, as in its wake came the Flagellants with their hatred of the clergy, their attacks on dogma and their contempt for the established Church. To the same epidemic may be partly ascribed the modern persecution of the Jews. The Crusades had already started the work, but the Flagellants poured new oil on the flames, blaming the disease on well pollution by the exiles from Palestine. To the Black Death is also to be traced the Peasant War which became so menacing in England in Richard II's time.

One of the things that imperilled the success of the Reformation was the fact that Emperor Maximilian succumbed unexpectedly to an attack brought on by his rage at a tavernkeeper's dunning, thus permitting a far more powerful and religious prince, Charles V, to ascend the throne. The bloody Thirty Years' War probably owed its immediate inception to the emperor at the time, Rodolph, being afflicted with insanity. The king of Spain, for a fact, joined in the fray because he was recovering from a nearly fatal illness and feared the fires of hell, should he allow the Protestants to conquer. In the same war, Tortensen, the Swedish marshal, could have taken Vienna, and maybe put an end to the contest, had not plague made enormous inroads into his forces.

Frederick II of Prussia was on his last legs, surrounded by victorious French, Austrian and Russian armies. A colic, caused by a surfeit of brandied cherries, changed the outlook overnight. Frederick's bitter enemy, Czarina Elizabeth, was no more. The "three women's" coalition came to an end. The Prussian ruler could hold his own against Marie Therese's demoralized troops and Louis XV's or rather Pompadour's carefree generals. When Austrians and Russians had the Turk practically at their mercy in 1789, a severe outbreak of plague compelled Austria to sign a disadvantageous peace treaty, instead of cutting short the Sick Man's case.

For the first time in her existence, England seems afraid in the latter part of the sixteenth century. Through Dutch merchants and British privateers, news filters of a mighty fleet assembled by Philip. In the Low Countries, gallant Farnesio gets ready his army. The first seaman of the century, Don Alvaro de Bazán, Marquis of Santa Cruz, dies unexpectedly, fresh from his conquest of Portugal, just after writing that he still felt strong enough to subdue other kingdoms for his master. The command of the Armada fell into the incompetent hands of a landsman, the poor duke of Medinasidonia, and alas! the Invincible was all but that.

One reason why all Spanish settlements developed at first so poorly in America was the overhovering menace of disease. Such was the toll exacted that of the two hundred men who sailed with Megalhaes around the world, only eighteen returned. A number of them, though, including their bold leader, were killed in battle with the Filipinos. A mortality of forty and fifty per cent. among the crew and passengers was nothing strange in crossing the ocean. Epidemics also played havoc with the first English settlements in this country and delayed fully fifty years the development of selfsupporting colonies. In fact, who knows that America had to be rediscovered precisely because of disease? When Columbus visited Scandinavia in 1477, not only had all memory been lost of Leif's Western colonies, but nothing had been heard for years of the Greenland settlers. The Black Death had just carried off half the population of Norway, and there was a surmise the same fate might have attained all the Greenlanders. The last Spanish colonies were also chiefly lost through disease. Spain poured troops into Cuba without ever getting within reach of her goal. No sooner were they landed than the yellow jack prostrated them. The fatalities caused by the mosquito have been computed at not less than one hundred thousand from 1854 to 1898. There is much point to General Wood's phrase that the eradication of yellow fever alone justified the Spanish-American War. Tropical scourges likewise kept Lesseps from completing the first interoceanic canal. This, in a way, was rather lucky, as the Panama passageway in the hands of France would have brought sooner or later a clash with the United States, the one nation really capable of holding in her strong grasp the keys of the two oceans.

Take the greatest of all past wars—the Napoleonic cycle. Some future St. Simon will some day elucidate how much of Napoleon's success was due to the fact that at the very moment he picked the crown from the gutter, every other European throne was filled by either an insane or a feebleminded ruler. During his whole career disease was going to make its influence curiously felt. Hoche, the one man who could block his way, died suddenly. At a critical moment, the enemy was beaten at Dresden. The victory had to be pushed at all costs, as everything hinged on the result. Napoleon was taken sick with cramps, first blamed on poisoning. The pursuit lagged, the Allies reorganized and Austria joined the coalition which defeated him completely at Leipzig. At Waterloo, victory seemed again within his grasp. Yet a peculiar ailment slowed his movements. The old lightning strokes were no more in evidence. The triumph at Ligny was not completed; the battle at Mt. Saint Jean did not begin until 11 o'clock a. m., thus giving Blucher a chance to arrive. Back in Paris, the same indecision characterized the emperor's actions. He was ill, really ill, as his sufferings at St. Helena were soon to prove.

The great captain could well laugh at the English expedition to Walcheren, where "fever will dispose of them." And yet he was blinded to the fact that in his two greatest enterprises, the Spanish War and the Russian Campaign, disease turned the tables on him. In Spain, it has been figured out that while he was deprived of about ninety thousand men by wounds, his losses from disease amounted to three or four hundred thousand. Imagine what that would have meant in the 1814 days so gloomily portrayed by Meissonier. Against that undertow, what booted the tireless efforts of "the most virtuous man that ever lived," Larrey? Much has been made of the vast casualties in the Moscow retreat, forgetting that more soldiers fell prey to dysentery and typhus fever than to the bullets. The imperial eagle, so frightfully singed at Moscow and badly frozen at the Beresina, was actually eaten alive by lice on its flight through the plains of Poland and Germany. One of the arguments advanced by Alexander to convince Napoleon that Russia should have Constantinople—one of the points on which their alliance broke—was the constant introduction of plague into his southern provinces from Turkey. In fact, what turned the Muscovite peasants against the French were the epidemics both in Southern Russia and Courland and Livonia—the latter really imported by prisoners in 1807—which were regarded as a divine punishment for the French alliance. On the other hand, Napier in his *History of the Peninsular War* did not hesitate to express his conviction that, at the battle of Victoria which sealed Napoleon's fate in Spain, success had been due to the physicians' efforts, putting five thousand sick veterans on their feet. This full corps added to Wellington's army had saved the day. Napoleon, by the way, always believed that Fox's untimely death had been one of the worst misfortunes of his career, as it had prevented France and England from coming to an agreement.

Half a century afterwards, Bonaparte's successor and namesake was also going to lose a decisive battle, prostrated also by a physical disability, stone in his case. His case led Zola to comment ironically whether a few drops of sand in a person's body were the factor that determined an empire's fate. Daudet has described vividly in his *Nabob* the death of the strong man of the period, Morny, which the author blames on poisoning, although it was most likely due to exhaustion caused by pleasure and high living. To Morny's premature death many traced the downfall of the imperial regime, as his influence might have counterbalanced the Empress' and prevented the Franco-Prussian War. A few years afterward, the new born republic breathed anxiously. Her former ruler was reputed to be again trying his skill on horseback. The imperialists boasted openly of the impending coup d'état, and their fearless mouthpiece, Paul de Chassagnac, shouted in parliament their hopes of seeing their master chase *"ces gens par la fenêtre."* Disease was, however, stalking his prey. The old trouble recurred, Napoleon had to be operated upon and he did not survive. The republic was safe. In the Crimean War the mortality from disease largely influenced the same ruler into signing an early peace—although perhaps not so much as the fact that he had already secured all the aims that led him into that useless venture. Mills regretted that Orsini's bombs had missed their mark, as the Franco-Prussian War would then have been avoided. And yet, eliminate tuberculosis from the King of Rome's system, and Napoleon III would have never been heard of. Had Albert's physician not blundered and the Prince Consort been spared by typhoid, perhaps his prestige might have been sufficient to stop that most avoidable of wars. Practically his last act had been to veto a message that might have brought war between his adopted country and the United States.

In turning the pages of history, who can ignore the significance of those attacks which at telling times took in Rome, Sulla out of Cæsar's path, Germanicus and Drusus out of Nero's; in England, the Black Prince out of Henry V's, Henry V out of Warwick's, Henry VII's elder son out of Henry VIII's, Edward VI and Mary out of Elizabeth's, Pym and Hampden out of Cromwell's, Cromwell out of Charles II's, Prince Frederick out of George III's, the four sons of George III and their issue out of Victoria's, Pelham out of Chatham's, Canning out of Peel's, Bentinck out of Disraeli's, Sydney Herbert out of Gladstone's, Campbell-Bannerman out of Asquith and Lloyd George's, and finally, Bonar Law out of Baldwin's; in France, Carloman out of Charlemagne's, Charles VIII out of Louis XII's and Francis I's, Henry II's sons out of Henry IV's, Louis XIV's son and grandsons out of Louis XV's, Louis XV's son out of Louis XVI's, Mirabeau out of Danton's and Robespierre's, Hoche out of Napoleon's, the King of Rome out of Napoleon III's, and Gambetta out of Clemenceau's; in Spain, Ferdinand and Isabella's son out of Charles V's path, Charles II out of Philip V's, Ferdinand VI out of Charles III's and in Germany, to go no further, Frederick William out of Bismarck's way, and Wilhelm I's son out of the last Kaiser's way.

Let this cursory sketch that barely grazes a fertile ground show the transcendent influence on history of a factor seldom studied and usually neglected—disease. Finally, let us not forget the curious paradox that all modern sanitary work, that wonderful fabric of health insurance, disease prevention, child welfare, infant hygiene, hospital care, increased expectancy of life, prophylactic vaccination, nursing service, early diagnosis, tuberculosis sanatoria, that has redeemed the tropics for the white race, lengthened the span of human life, and deprived many diseases of their terrors, had their origin in those early onsets of cholera, plague, yellow fever, and typhus fever, which led to the appointment of boards of health and promoted the enactment of sanitary legislation.

NOTES.

1. Permitted English to conquer Egypt.
2. Turned Russia from Napoleon's into his enemies' camp.
3. Decided Enghien's shooting, and as a protest, a European coalition.
4. Strengthened German resistance to Napoleon.
5. Divided Serbia into armed camps.
6. Put new life into the Holy Alliance.
7. Ultimately caused the 1830 revolution.
8. Ended Bolivar's influence in South America.
9. Infuriated the Greeks and eventually led to Russian intervention.
10. Converted Greece from a republic into a monarchy.
11. Confirmed the repressive policy which finally caused Louis Philippe's dethronement.
12. Stopped Pius IX's liberal policy.
13. Led Napoleon III to interfere in Italy and nearly brought a clash with England.
14. Bombardment of Japanese ports by the British and reversal of anti-foreign policy.
15. Alienated the South for a whole generation.
16. Confirmed Alexander II in his distrust of France.
17. Discredited the Second Empire and paved the way for the revolution.
18. Settled the fate of Amadeus' rule.
19. Gave Bismarck a chance to enforce his anti-socialist laws.
20. Placed ultimately Abdul Hamid on the throne.
21. Committed Russia to a reactionary policy.
22. Delayed Irish selfgovernment.
23. Brought eventually the democrats into power.
24. Changed Bulgaria from pro-Russian into pro-Austrian.
25. Made Nicholas II a confirmed anti-Japanese.
26. Permitted the Dreyfus affair.
27. Eventually permitted the Spanish-American war.
28. Allowed Germany to seize Kiauchau.

Taoist Ideas of Human Anatomy.—E. V. Cowdry, Ph. D. (*Annals of Medical History*, December, 1921), who is connected with the anatomical laboratory of the Peking Union Medical College, begins his article with an interesting account of the numerous difficulties encountered before access could be gained to the sacred precincts of the most complete and secret library of Taoist medical and literary works, situated about half a mile outside one of the gates of Peking. He describes also the fine old priest in charge, to whom they presented a photograph of himself, which delighted him immensely because it showed the sunshine reflected brightly from his shiny black silk hat. This brightness he declared to be the flame of his own intellect, which no one before had ever succeeded in photographing.

The central idea of Taoism, greatly preverted as it has been from the original teachings, is demonism. Great attention is paid to animals. In fact, one of the great temples is an asylum for old and decrepit pigs and certain kinds of birds, which are maintained in luxury till they die. Each of the six organs of the human body is thought to be inhabited by an animal, as is represented in one of the books in the library. A white tiger lives in the lungs, a turtle and a serpent in the gallbladder, a dragon in the liver, a phœnix in the spleen, a red bird in the heart, and a two headed deer in the kidneys. The *Nan Ching,* written by Li Chung in 1269, is probably the most valuable book in the collection. It contains diagrams of the viscera, shown anteriorly and posteriorly. In these drawings, curiously, everything is transposed, the liver being shown on the left, and the spleen on the right. Another drawing illustrates the close and elaborate relationship of spirits and genii to the human body; another shows where the pulse should be felt at the twenty-four different times of the year—in summer near the fingers, and in winter far up the arm. One design traces differences in temperature in the various parts of the body. At the head is shown a broken line between two solid lines, which means fire, and at the feet, a solid line between two broken ones, which means water. Going up toward the head the temperature increases, the reason why clothing is not needed to protect the head from cold. The other signs in the drawing indicate combinations of male and female principles. The pure male principle, three solid lines, stands also for Heaven; the female principle, three broken lines, represents earth. Proper combination of these principles is essential for life and happiness. In disease, the malicious excess of one or the other principle is removed by inserting needles of great variety into the body in definite localities. Teachings such as these prevail throughout China in many localities, although the numerous religious beliefs of the country have altered some of the older practices in certain regions.

THE PENETRATION OF THE ORGANISM BY NEMATOIDEA THROUGH THE INTEGUMENT

For years past and until some two decades ago, it was generally admitted that parasites of the worm class entered the human organism by the natural orifices, especially the mouth. However, such is not always the case, because it has been shown that several intestinal parasites reach their abode through the cutaneous surface.

Thus, in 1898, Looss demonstrated this process with the larva of ankylostoma, although he made this discovery upon his own person and somewhat by chance. The reality of this route by direct penetration has since been confirmed by numerous observers. Looss also showed that this manner of penetration is likewise true for Strongyloides stercoralis and at a later date Gornez de Faria, Feitosa and Smith demonstrated penetration of the skin by Necator americanus. A similar demonstration has been made in the case of stephanurus.

Brumpt, of Paris, has recently shown that certain tissues attract the larvæ of some nomatodes and allow them to make a transit through them. This fact has already been proved in the case of the parasites mentioned above, but only in the case of monoxenous parasites. Nevertheless, this likewise applies to other parasites which undergo their evolution in an intermediary host and still follow the cutaneous route for entering the organism. Among them Filaria bancrofti may be mentioned. The larvæ of this parasite are transmitted by various mosquitos, but they are not inoculated by the bite of the insect as is, for example, the plasmodium of paludism. They are merely placed upon the surface of the skin by the bite of a contaminated mosquito usually by rupture of the labium or sheath of the proboscis. Thus placed in contact with the skin, the larvae of the filaria actively penetrate through the integument and it is probable that the larvae of Filaria loa do the same, while it has been proved in the case of Dirofilaria immitis, which is a parasite of the dog.

The passage of larvæ—no matter which—through the skin is not effected without setting up local reaction, such as dermatoses resembling attacks of urticaria, with redness and itching and occasionally papulovesicular or pustuloulcerating eruptions, the latter being due to secondary infection. The cutaneous manifestations arising from the penetration of the larvæ of ankylostoma and necator are especially encountered in warm damp climates in subjects who walk and work with naked feet.

Finally there is one point to which Brumpt calls particular attention and that is that these human vermin dermatoses may also be due to adult nomatodes of various animals. These are capable of producing cutaneous lesions in man and inversely, the larvæ of nomatodes—parasites of man—may cause cutaneous lesions in animals but in their ordinary host they never attain full development.

THE ETIOLOGY OF CUTANEOUS PIGMENTATION

The pathogenesis and etiology of cutaneous pigmentation is unquestionably interesting but not well known and the divers notions we possess are, to say the least, very hypothetical. The appearance of dyschromias appears to be related to external and internal causes, the former being the varieties best understood. It is known that any irritation, when somewhat intense and prolonged, can give rise to pigmentation of the skin but as Darier has pointed out these pigmentary disturbances have, for the most part, the character of vital reaction against an irritant and, consequently, their manifestations and intensity will depend less often on the nature of the causal agent than on the reactionary tendency of the subject.

Among the irritating causes, physical agents play an important part. For example, the production of sunburn is principally due to light and in particular to the chemical rays of the spectrum. Heat may be the factor in some cases and Neisser incriminates the caloric action of furnaces in cases of syphilitic dyschromia, occurring in blacksmiths and bakers. In the same way, mechanical agents can give rise to pigmentation, or at least, play a secondary part as a localizing agent. Vitiligo and the socalled primary pigmentary syphilide are very frequently localized in areas chronically irritated, as has been shown by Thibierge and Finger.

Finally, to conclude with the external causes, besides the parasitic dyschromias, whose etiology seems to be complex, it may be complex, it may seem logical to include those which are secondary to the dermatoses such as the bullæ of pemphigus, herpes, zona, boils, papulonecrotic tuberculides, etc., as well as syphilitic lesions. The macula of roseola, secondary papules and ulcerating lesions are the starting points of pigmentary change in which either a melanoderma or a more or less atrophic leucoderma are observed.

But still other causes of dyschromia have been involved both general and internal, whose mechanism has been very diversely interpreted. Among them hyperemia should be first mentioned as it unquestionably intervenes in pigmentations having a local or external cause, as, for example, the melanoderma occurring on varicose limbs. Lesions of the suprarenal capsules have for some time been recognized as a cause of melanoderma of Addison's disease but space forbids a discussion as to what extent renal insufficiency or lesions of the pericapsular nervous plexus acts as factors. If suprarenal insufficiency be incriminated it should be pointed out that normally the suprarenals destroy pigment or a pigmentogenous substance and that when diseased, they cannot do so. Or if the sympathetic theory be maintained, it will be said that when irritated, a hyperactivity of ing from the Spirocheta pallida.

The sympathetic and cerebrospinal systems undoubtedly play a part in many dyschromias, as in leprosy, vitiligo and the socalled primary pigmentation of syphilis. The latter does not belong exclusively to lues because it has been observed in tuberculosis and chlorosis. On the other hand, in many ways it is similar to chloasma of pregnancy and Addison's disease and it may well be asked if the syphilitic dyscromia is not also consequent upon some disturbance of the pericapsular nerves resulting from the spirocheta pallida.

Other dyschromias have been regarded as due to hematic changes, such as malarial melanoderma and perhaps bronze diabetes. According to Diday, the blood of syphilitics undergoes a peculiar change in its coloring matter which allows it to become deposited in the tissues. If for any reason a congestion arises with a consequent increase of the blood in the skin, it will progressively infiltrate the integuments and finally the coloring matter will come near enough to the surface to produce a perceptible change in the hue. Petresco likens the mechanism of the pigmentary syphilide to that observed in paludism; there is an exaggerated deposit of hemoglobin coming from the destroyed red blood corpuscle, hence melanin and its deposit in the tissues. Other observers have thought that the presence of bile pigments in the blood might be the origin of a good number of dyschromias and perhaps syphilis, which does not spare the liver, produces pigments in this way. Finally certain disturbances of pigmentation have a toxic origin, such as arsenical melanoderma and argyria.

Although the etiology of dyschromia is poorly understood, the process can be divided into primary and secondary types. The first—or spontaneous type—is not preceded by any eruptive element. On the contrary, secondary pigmentations are those succeeding an eruptive element which was seated at the spot where the dyschromia—melanoderma or achroma according to the case—ultimately arises. In the first group can be placed the melanoderma of Addison's disease, lentigo and chloasma of pregnancy. In the group of secondary dyschromas are the melanodermas or achromas following some local dermatosis, such a pemphigus, lichen planus, varicose ulcer, etc.

HISTORICAL THOUGHT IN SCIENCE

On another page Dr. Moll has made a very suggestive contribution to historical thought in science by upholding the thesis that representative men, as Emerson calls them, have altered the course of history. He falls in line with a school of historians who have frequently, though incidentally and in rather desultory fashion, given their adhesion explicitly to the same doctrine. It is to be doubted, however, if they are the most numerous or will represent the general trend of modern thought on the subject. It is difficult to deny, of course, that if Napoleon had died on the bridge of Lodi the civil jurisprudence of France and its admirable cohesiveness would not have been what it is today. It is less difficult to assert the evanescence of his conquests, bought at the expense of such a squandering of blood and treasure as sinks into insignificance only in the events of a hundred years later. He left his glories for his countrymen to gloat over, of course, but he did not give birth to the Frenchmen's love of *gloire* or his pride of race, his admirable virtues and his amiable vices. These are, however, matters for the historians to discuss and not for other professions to decide.

When we consider the career of Alexander we find ourselves in closer touch with the history of science and of medicine as a part of it and we see more clearly that man's destiny is greater than man. There is a determinism which guides it, whose laws are more evident than those a certain school of biologists, the old school of orthogenesis and its modern representative in the persons of Bateson and Keith, have intimated may yet be discovered for living things. One can easily perceive from the pages of Xenophon and Herodotus that the Oriental world was a giantess tottering to its fall even in their time and that the hardy sons of rock bound Greece were sure sooner or later, not alone to stop her, as they did at Marathon and Platæa, but to shatter her power far within her own boundaries. So Charles Martel did at Poitiers and Tours and Napoleon under the Pyramids, the former when Arab orientalism was held back from the mountains and valleys of Central Europe, the latter when he brushed aside the Mamelukes. We see dimly enough perhaps, but yet we can not fail to comprehend that forces, more or less ruled by biological and physical laws, shape the fate of nations and civilizations and man, however transcendent his ability, is but the instrument of a generation which gives birth to a new generation and a new instrument to keep them true to their destiny, shaped by the laws of Nature.

There is a curious reciprocation in the advance of science, in the ebb and flow of mighty forces fighting in the pages of history, which sometimes escapes detection—the east against the west, but there seems no doubt we of the west derive through the Nature Philosophers of the Asiatic Greeks the beginnings of our western science. There seems scarcely less doubt that these men did not create their cosmic theories *de novo*. They quite evidently had them from the oriental civilizations of Babylon and Egypt and India, perhaps China. Three hundred years later, so Dr. Moll thinks, the death of Alexander arrested the destinies of civilization. I am not sure he means they were more than arrested. It could not have been for long. He but pricked the hollow bubble, which appeared so solid to Herodotus and Xenophon, but he carried in his train the savants of Greece to the East, as Napoleon carried the scientists of France to Egypt. The latter carried back these flowers which had sprung up from the clumsy carcass of Arabian orientalism, which in its turn had fed on the science of Aristotle and Galen and we, almost in our day, have passed the torch on to Japan and now to China. In the mighty dash of forces like a shuttlecock or the foam of the sea science has been kept in the air passing back and forth, and in the face of these forces Napoleon and his great predecessor, Alexander, look puny indeed.

In this mighty battle of forces, they, like the phantasmagoria at the mouth of Plato's cave, silhouetted against the gloom behind them, are seen by the student of history, if he is successful in synthetising its lessons. We find the historians of medical science in confusion as to whether the Hindu Susruta is an oriental corruption of some of the books of the Hippocratic Corpus carried to them by the medical staff of Alexander's forces or by those who followed in their wake as far as the Ganges, or whether the Hippocratic books, long before Alexander, had derived their lore from the science of the East. As to this all the impartial student can assert is that surely one spring of knowledge was diluted with the waters of the other, indeed deeply impregnated, for some of the passages can be almost literally rendered by the lines of the other. When we take up the records of the Arabians and what they handed on to Europe—Rufus of Ephesus for instance—we are again baffled to know which is which, what is oriental and what is occidental science. History in these instances, and in many like them, supplies us with a commentary on Kipling. East may be East and West may be West, but neither the seven wise men of ancient Greece nor the seven times seventy wiser men of modern science have been able to disentangle the fringes of history woven by mightier hands than those of Alexander, or Cæsar, or Napoleon.

HOSPITALS FOR CHRONIC DISEASES

One of the many misconceptions concerning institutions for chronic diseases is the idea that patients in these hospitals require only elementary nursing care. Indeed, the excellent report issued recently by the Committee on Nursing Education recommends that such institutions are the proper sphere for trained attendants. In a recent article it has been pointed out that many of the inmates of hospitals for chronic diseases require highly skilled and specialized medical and nursing care (Nursing Service in Hospitals for Chronic Diseases, Ernst P. Boas, *The Modern Hospital,* August, 1923). It is well known that in too many cases they have been left in the charge of ignorant and unskilled attendants. A properly conducted and equipped hospital for chronic diseases must be manned by a large number of skilled and conscientious graduate nurses. Such an institution, if it is of sufficient size, offers excellent material for the education of pupil nurses, if proper affiliations are arranged. The psychology of a chronic patient differs considerably from that of a patient ill only a few weeks. A nurse who has learned to handle such a patient is better qualified for all branches of her work than is the nurse acquainted only with patients suffering from acute disease.

The present tendency in nursing circles to provide better education for pupil nurses is directed largely by the desire to produce well trained young women for public health work and for the administrative nursing field. In the enthusiasm of the moment the need for the conscientious bedside nurse who has learned the art of alleviating the suffering of individual patients is largely overlooked. The report on the nursing needs of institutions which care for chronic patients is therefore very timely, emphasizing as it does a wider sphere of usefulness for the ordinary trained nurse. The leaders in the field of nursing education while striving to increase the educational opportunities for the more specialized type of nurse must keep in mind the undiminished need for a large number of well trained and conscientious bedside nurses.

THE NATURE OF PLASTIC LINITIS

The nature of plastic linitis—Brinton's disease—has been the object of much discussion, some observers regarding it as a purely fibrous process, others considering it epithelial in nature. Both these opinions have been defended with numerous arguments in their favor. A purely fibrous linitis may really exist in the same way as an infiltrating carcinoma of the stomach, erroneously described, we think, by the name of cancerous linitis. Brinton thought that linitis was caused by the deposit of a plastic substance between the meshes of hypertrophied connective tissue, and he also pointed out that muscle, connective tissue, and mucous membrane all assumed an abnormal aspect and stated that it was clear that all these structures owed their increase in thickness to the presence of the same substance whose uniform infiltration was one of the principal characters of the lesion. A deposit is found whose slow but fatal action attains all the gastric layers and produces a thickening of the muscular stratum of the organ. Brinton and others have endeavored to distinguish this process from malignant disease.

According to Brinton, Lebert and Broca, the tunics of the stomach remain quite distinct, the muscular fibre is usually respected; there is condensation and retraction of the tissue of the stomach *en masse,* giving the organ the consistency of cartilage. No gastric juice can be expressed, the lymph nodes are intact, there is no trace of epithelial elements, the infiltrated tissue is unlike the stroma of cancer (Brissaud) and nowhere does it interfere with the vitality of the normal cell elements (Brissaud).

The partisans of the epithelial theory—among them Chauffard—point out that linitis is prone to occur between the age of thirty to forty years, it is not preceded by any form of gastritis and its evolution is much more rapid than gastritis. Analysis of the gastric secretion shows an absence of free hydrochloric acid, and although leucocytosis does not exist it must be recalled that this only arises in the advanced stages of gastric cancer at a time when the growth has undergone ulceration. Bret and Paviot attach much importance to the fact that linitis occasionally extends to the transverse colon and the mesocolin. They also regard plastic linitis as cancerous in nature, from the fact that they found isolated islands of round cells in the submucosa, assuming a protoplasmic atmosphere in the transverse colon and frankly epithelioid in the ovary.

As a third argument these observers maintain that the lesion in the submucosa is not a sclerosis. In the first place, the submucosa is the route for an easy extension and is therefore chosen by infiltrating gastric cancer. Secondly, if the process were a sclerosis secondary to chronic gastritis, why they argue, should the sclerosis be more marked in the submucosa than in the mucosa itself? Why is the oldest sclerous tissue—the nearest to the adult type—not in the interglandular spaces? Why does this extensive sclerosis of inflammatory origin never present the completely adult type of connective tissue and is the only tissue found that all observers unanimously qualify as fibroid, and never presents large connective tissue fibres brightly stained by carmine? In reality, at the base of the mucosa is seen rows of young cells deeply stained, with an almost continuous extension sending off brightly stained prolongations between the muscular fasciculi of the mucosa and then become lost in the submucosa, without any trace of adult connective tissue fibres. It is in the gastric subserosa that this fibroid tissue is found, and, as Garret has pointed out, the lesions of the mucosa are distinctly consecutive to a submucous neoplastic process and not so old. In the cases studied by Brinton, he insists upon the integrity of the mucosa and states that the functions of secretion have, so to say, not undergone any change.

Clinically, plastic linitis ends like ordinary gastric cancer in the vast majority of cases. After a more or less long period of insidious and badly defined digestive disturbances, which might be attributed to chronic gastritis, rather sharp and frequently spontaneous pain occurs in the epigastrium and hypochondrium. At the same time there is vomiting of food or mucus, the vomitus rarely being bloody, and hematemesis of any considerable amount is uncommon. The general health quickly declines and the progressive, fatal evolution of the process ends in death between eighteen months and three years.

Briefly expressed, the term plastic linitis must be reserved for those cases only in which the fibrous infiltration of the stomach is devoid of any trace of epithelial elements.

SOUND TEETH

A distinguished clinician has made the statement that we know little about personal hygiene. It is an unusual remark and is not so far from the truth as might be supposed on first hearing. In regard to the teeth, however, we are learning by leaps and bounds and are getting certain of facts which sound new but are very old—facts that should have been evident to anyone not raised a human being. We have special reference to the most common of all diseases—dental caries, and to its cause and prevention.

An experiment on a large scale was carried out by Dr. Fones in the Bridgeport schools. For five years a large group of specially trained dental nurses were set to work cleaning, by precept and practice, the mouths of the school children. Work was begun with the first grade children. At the beginning of the experiment the children showed an average of seven cavities per child. At the end of five years, or when the children had reached the fifth grade of school and about the twelfth year of life, it was found that, with the daily use of brush and paste, and the special cleanings by the nurse once or twice a year, the children averaged 4.6 cavities per child. Apparently something had been gained, but only apparently. Dr. Wheatley, of Shropshire, England, examined the mouths of 2,217 untreated school children from six to seven years of age—or at the period of our first graders, and 1,417 children, also untreated, at the age of twelve. The former had an average of 7.1 carious teeth per child, and the latter 4.95. A study by the New York Association for Improving the Condition of the Poor showed a similar decline in children with uncleaned teeth of from seven cavities at five and 6.7 at six to 4.7 cavities at twelve years of age. In other words, the drop in number of carious teeth per child in these untreated children was practically the same as in the Bridgeport children who had been scraped and brushed.

Now comes Dr. DeW. Cross, director of the Forsyth Dental Infirmary, and says (what we ought to have known) that proper diet on the part of the mother and on the part of the child "are the things that make teeth, and not the use of the tooth brush. Mothers, before the baby comes, must take the responsibility of giving good or bad teeth to their offspring, and before six years of age the whole question of good teeth for life will have been decided." All adult dentistry diseases, except pyorrhea, are the result of poor teeth development or neglect of proper diet and hygiene during childhood.

As for the tooth brush and tooth paste, they are placed by these definite facts of hygiene in the same class with soap and wash cloth—tools to make a man feel better and more agreeable to society but not more healthy than if these means of cleanliness were unknown. We might have learned as much, by consulting the wild animals, long ago.

VALUE OF SAFETY CAMPAIGNS

During the last few years many cities have made a special point of accident prevention work in their industrial plants, and the results have been very striking. An outline of this work, particularly that in St. Louis, was given by C. W. Price in an address during safety week, recently celebrated in that city. In 1917, industrial accidents were responsible for the deaths of 110 workmen in St. Louis; in 1922, only fifteen were fatally injured, in spite of the large increase in the number of employees. This result was attained through intensive educational work along safety lines in individual plants and also through a community safety campaign, which, it was easy to see, greatly influenced many workmen to adopt safe practices in their work and to avoid and condemn unsafe ones. Another example of this decrease in hazards was shown in the record of the Ford Motor Company of Detroit, which in 1920 had but one fatal plant accident among the fifty thousand employees, while ten workmen lost their lives outside the factory.

There has been also an increasing interest on the part of employers in commercial traffic, probably because of the fast increasing number of business vehicles on the streets, and also because of the increasing cost of public liability insurance. The chief methods recommended by Mr. Price were systematic daily safety instruction in the public schools, a continuous poster campaign on the streets, and a well arranged campaign in the daily press. Probably one half of all that can be done in any community to reach the adult population is to be effected through the safety education of the school children, who carry the safety message home to their parents.

Washington, it was stated, has very successfully worked out the socalled visualizing of safety on the streets. Slogans with short, pertinent messages are displayed on street corners, at filling stations, on street cars, busses, and taxicabs, on school houses, public buildings and factories. These are changed monthly, and the superintendent of police reports that in two months the total number of accidental deaths has been reduced thirty-two per cent., traffic deaths forty-three per cent., and those of children sixty-five per cent.

THE ILLEGITIMACY ACT OF NORWAY

An article in a recent number of the *Journal of Social Hygiene* discusses the working of the widely known Norwegian illegitimacy law, called the Castberg Act. It reports that it is the consensus of opinion among officials in Christiania that the results are very satisfactory. Illegitimacy has not increased, the law has given no occasion for blackmail, and the condition of illegitimate children has been greatly improved since the passage of the law in 1915.

This act provides that the State becomes responsible for establishing the paternity of the child, and for its maintenance. The mother reports to the local authorities, who see to it that the father, except of course in certain cases, supports both mother and child. This support must be in accordance with the means of the better situated of the parents. Maintenance is required for the child until the sixteenth year, sometimes longer. The mother is required to share in this support if her circumstances permit, and the child inherits from the father's line as well as from the mother's, but the property relations of the husband and wife are changed to prevent any child that may be born out of wedlock from inheriting from either spouse property that has come into the marriage through the other. If the father should default or abscond, the State cares for mother and child and there is no loss of citizenship attached to relief in such a case. If the child's paternity cannot be established, two or more men, either of whom may be suspected to be the father, may be ordered to contribute to its support. Needless to say, severe penalties are provided for a mother who accuses a man falsely of being the father of her child.

Obituary.

P. W. LATHAM, M.D., F.R.C.P.,

London.

A short time ago the death was recorded of Dr. Arthur Latham, the well known authority on tuberculosis, and on October 29th, his father, Dr. P. W. Latham, for twenty years Downing Professor of Medicine at Cambridge University, died at Clifton, Gloucestershire, about a week after completing his ninety-first year.

Peter Wallwork Latham was born at Wigan, Lancashire, on October 21, 1832. His father was a medical man. He was educated at Wigan and for a time was apprenticed to his father. At that time apprenticeship was part of the medical curriculum. He then entered Glasgow University and afterwards Cambridge University. In the Mathematical Tripos of 1858 he was nineteenth wrangler, but was more successful in the Natural Science Tripos of 1859. He was one of the two in the first class and gained distinction in five subjects. After travelling in Germany he was appointed assistant physician to Westminster Hospital, from which position he resigned in 1863 to fill the offices of physician and clinical lecturer at Addenbrooke's Hospital and medical lecturer at Downing College, Cambridge. When he first returned to Cambridge, Latham interested himself in tuberculosis, a line which his only son, Arthur, afterwards followed with great distinction. In 1860 he was elected to a Fellowship at Downing College and in 1874 was made Downing Professor of Medicine, a post which he held until 1894.

As a lecturer Dr. Latham was very successful and commanded the respect of the students. He was a sound, able and accomplished physician of fine and dignified presence and with kindly and courteous manners. As a writer Latham was not prolific, but what he did write was well worth reading. His leaning towards the chemistry of the body is exhibited in his Croonian Lectures, in which he discusses the pathology of rheumatism, gout and diabetes, and again in his Harveian Oration. He formulated a highly ingenious but impracticable theory concerning the molecular structure of living protein. He contributed articles to Quain's *Dictionary of Medicine* and various papers on the symptoms of phthisis, the etiology, pathology and treatment of typhoid fever, the formation of uric acid in animals and blood changes in disease.

LIEUTENANT COLONEL LEAVITT

United States Army.

The Adjutant General's Office of the State of Nevada has sent out memorial resolutions on the death of Lieutenant Colonel Granville Ernest Leavitt, who met death by drowning on September 17, 1923, while on a hunting expedition. Dr. Leavitt was born in California in 1872 and was a member of the governor's staff. He was given a military funeral.

News Items.

Dr. S. Josephine Baker Appointment.—Dr. S. Josephine Baker, of New York, has been appointed consulting director in maternity and child hygiene of the United States Children's Bureau, the Department of Labor announces.

Dr. Shuman Back in America.—Dr. John W. Shuman, formerly director of internal medicine at the American University of Beirut, Syria, is now engaged in private practice in Los Angeles, Cal. He is associated with Dr. Carl E. Conn and Dr. A. M. Pond.

Third Harvey Lecture.—Dr. Walter A. Jacobs, of the Rockefeller Institute for Medical Research, New York, will deliver the third Harvey Society lecture at the New York Academy of Medicine, on Saturday evening, December 8, 1923. His subject will be Chemotherapy of Protozoan and Bacterial Infections.

Post-Graduate Medical School Lecture Schedule.—The following lectures on Friday afternoons at 5 o'clock at the New York Post-Graduate Medical School and Hospital are announced: December 7th, The Importance of Early Diagnosis in Diseases of the Genitourinary Tract, by Dr. Joseph F. McCarthy; December 14th, Radium Therapy (with moving pictures), delivered by Dr. George S. Willis.

Riverside Medical Society Organized.—The Riverside Medical Society of the City of New York has recently been organized, made up of physicians located in the West End section of New York City. The society has for its object the advancement and study of medical and kindred sciences as well as the promotion of good fellowship among its members through various social functions to be held during the year. The officers for the coming year are Dr. Isador W. Kahn, chairman; Dr. Martin Cohen, vice-president; Dr. M. Murray Peshkin, treasurer, and Dr. Samuel Morse, secretary.

President Coolidge Head of Gorgas Institute.—President Coolidge has accepted the honorary presidency of the Gorgas Memorial Institute of Tropical and Preventive Medicine. Many prominent physicians as well as leading figures in the nation comprise the board of directors. The Gorgas Memorial Institute will be established at Panama City. It will conduct research in all preventable diseases and train men and women to assist in prevention. An endowment fund of $5,000,000 is to be raised by popular subscription. The directors decided to start a drive to raise this fund on January 1, 1924.

Foreign Correspondence.

LONDON LETTER.

(*From our own correspondent*)

London, *September 18, 1923.*

NEW MINISTER OF HEALTH.

It seems but the other day that the announcement was made that Mr. Neville Chamberlain had been appointed Minister of Health. Nearly all the community and perhaps the medical profession especially were congratulating themselves that the minister possessed most of the qualifications which should go to make a successful holder of the position. Mr. Chamberlain, during the short time he occupied the ministry, amply fulfilled these rosy anticipations and everyone hoped that his stay would be long. But the exigencies of politics come before everything else.

The Ministry of Health is without doubt one of the most important Governmental departments, if not the most important, although unfortunately the public, through lack of knowledge, do not view it in this light, and it is against its smooth and effective working that its titular head should be constantly changed. Such changes tend to destroy or impair confidence in its powers for good. It is perhaps not in the best interests of public health that the department should be subjected to political influences, that is, to any great extent. It must be also borne in mind that the Ministry of Health has to deal with one of the most difficult problems of the day, that of housing. It is a burning question and one in which the strong Labor Party are intimately concerned and it may be said also that no question at the present time more closely affects the health of the people. If the population were properly housed there is absolutely no doubt that better health generally would result. Therefore, not only is a strong man needed in the Ministry of Health but moreover one who will stay in office long enough to carry out his policies.

The newly appointed Minister of Health, Sir W. Joynson-Hicks, has been in Parliament for some time and is regarded as a rising man, and it is to be hoped that he will retain his post sufficiently long to effect a few of the numerous reforms projected in the interests of health and housing reforms in particular.

PAYING PATIENTS IN A LONDON HOSPITAL.

King's College Hospital, one of the large London hospitals, is shortly to devote another ward to paying patients. This new departure for England was started in King's College Hospital purely as an experiment in 1921, when six of the ordinary wards had to be closed owing to shortage of funds. It has proved so great a success that it has been decided to extend it. The three existing paying wards provide accommodation for fifty patients, the new ward will bring the accommodation to over seventy, and there are also eight private rooms. Ward patients pay five guineas a week with an additional fee for the medical staff, which is fixed by the governor of the hospital. Those desiring private rooms are charged eight guineas a week. In the new ward curtained cubicles will be available at four and a half guineas a week. The system is a boon to small professional people and those who could hardly bear the strain of a private nursing home or a specialist's fee. It has, however, been thought by some that the growing number of private patients might detract from the original charitable purpose of the hospitals. All hospitals in Great Britain were founded as charities and remain so. On the contrary, it is stated that the extra income from paying patients actually enables the hospital authorities to maintain more free beds than otherwise could be done and helps to defray the enormous cost of equipment and so on. Also the hospital authorities are taking every precaution to avoid clashing with the interests of general practitioners, and with this end in view a scheme was being considered to allow general practitioners to treat private patients within the hospital whenever practicable. An attempt is also being made to devise a scale of charges which will include the staff doctor's fee, and so avoid the necessity for the fixing of this according to the patient's financial position. At present the fee is not left to the physician or surgeon himself, because it is found that he is inclined to be too generous, to his own detriment. In many cases, the patient's fees are paid by some corporate body, such as a church society, and the result has been most happy. From June 1, 1921, to August 31, 1923, paying patients in King's College Hospital numbered 1,293, compared with 12,635, a relatively small proportion.

CANCER CAMPAIGN IN GREAT BRITAIN.

Cancer, in spite of the advances which have been made, both in diagnosis and treatment, is still the most common single cause of death in persons over thirty years of age, and is becoming so in an increasing degree. During 1920, in England and Wales, nearly 43,000 persons of thirty and upwards died from cancer. In 1921, the last year for which the Registrar-General's figures are available, the corresponding number was 45,328. During that year one in every seven deaths from the age of thirty upward was caused by cancer. We are still ignorant both of the causation and the cure of cancer. Many other diseases have yielded their secrets to patient investigation, and there is no reason to suppose that the problem of cancer will not eventually be solved, yet thousands of suffering men and women, and those who suffer with them, are asking how long they must wait, and if there is nothing that can be done to hasten a discovery which will bring relief to those whose outlook is today so hopeless. The answer to this question is clear. The first step towards finding the cure of cancer is to discover its cause. To find this cause no effort must be spared. Every possible line of research must be diligently explored. More men must be set free to devote themselves wholly to research, and their work must not be hampered or prevented by want of money. Much research work is being carried on, and considerable advances have been made in the technic of operations designed to remove the disease in its early stages or retard its progress in more advanced cases. All honor is due to those who have or are doing the work, but a vast amount still remains to be done.

Impressed by the need for immediate action we have joined together to found a movement which will coordinate and support research on cancer throughout the British Empire. This new concerted movement will be called the British Empire Cancer Campaign. It will be governed and directed by an executive council, the members of which will act as chairmen of small working committees, each dealing with a separate aspect of the cancer problem. Medicine, surgery, human pathology, chemistry, physics, radiology, animal and plant pathology, hygiene and vital statistics will all be represented by committees, whose work will be coordinated by the executive council, acting, in fact, as a central clearing house. The council is anxious to make it clear from the outset that it has no wish to interfere with the work already being carried out. Individuals and institutions now working on the cancer problem will be helped and encouraged, and where practicable, financially assisted. In this way investigation can be carried out simultaneously along many lines, and the results of these inquiries will be brought into the common stock of knowledge. A discovery in any one branch will be made known to all, and may lead to discoveries in other branches.

It is in this coordination of effort that our most confident hopes are placed. No one can say with certainty that we shall succeed in our quest to find the cause of cancer, but a movement so broad must inevitably advance the knowledge which we have of this disease, and every step forward brings us nearer to our goal. The British Red Cross Society has placed its organization and machinery at the disposal of the council of the campaign, and a generous donor has already given a sum sufficient to cover the preliminary expenses of this appeal. All future contributions will, therefore, be expended in encouraging, assisting, organizing and administering systematic research and treatment on a scale that has hitherto been impossible. To do this a large sum of money will be needed, and we appeal with confidence to the British public in the United Kingdom, and in the Dominions and Colonies overseas. During the war we had ample evidence of the capacity of this Empire for united and intensive effort, and in no field was it more effectively shown than in the relief of suffering and the prevention of disease. Is it too much to hope that the same spirit will animate our people when they are called upon to wage war against an enemy that is in their very midst? We plead with all earnestness that we may be given the means wherewith to carry through the task which we have set ourselves to accomplish, and thus to bring relief and hope to those who lives are now darkened by suffering and despair.

Sir Thomas Horder, who is one of the most able physicians of the country, wrote in the Sunday *Times* recently on the campaign. He pointed out that this new effort in England, conceived upon a very broad and very intensive scale, was, if anything, overdue. The question at issue is a vital one; it is not a question for the doctors only, it is a question primarily for the community. He goes on to say that it is intended that the money subscribed to the fund through the Red Cross Society, whose splendid machinery is being utilized for the purpose, shall be disbursed in a number of ways. There is not only the question of laboratory research, there are the very large questions of accurate statistics of clinical bedside observations, of the collection and classification of literature for reference, and of the critical examination of methods of treatment advanced by members of the profession and of laymen. The Executive Committee of the campaign will act as a clearing house of information regarding all the aspects of cancer. At present no such clearing house exists; much work is being duplicated and the same avenues of research are being explored by different workers who are largely in ignorance of each other's efforts or of the results of similar work already done. The value attaching to the association of men of experience in several branches of medicine and science is obvious when it is realized that no one can say today from what quarter light may come. For this reason the field of inquiry is being made as broad as possible.

LATIN AMERICA NEWS LETTER

(*From our own correspondent*)

Balboa Heights, *November 12, 1923.*

PANAMA CITY MILK SUPPLY.

Dr. Henry Goldthwaite is the authority for the statement that there are few places in any country where the milk supply is purer than that sold in the city of Panama. The standard for the bacterial content of the pasteurized milk sold in the terminal cities is two thousand bacteria to the cubic centimetre and the greater part of the milk supply averages between five hundred and fifteen hundred. This compares most favorably with many cities in the United States, where the bacterial content is sometimes as high as one hundred thousand. A considerable proportion of the raw milk produced in the Panama district averages from ten thousand to thirty thousand bacteria to the cubic centimetre. The milk industry has expanded wonderfully in the past four years into the Sabanas district. Four years ago there was little or no system in the control of dairies and the first records kept of the twenty-five dairies at that time showed that their total production amounted to about forty thousand pounds of milk a month, or about seven thousand bottles of the size known as fifths, or five to the gallon. Owing to the improved milk code which the Health Department of the Panama Canal adopted, systematized hours of milking, and of cleanliness, and the stimulation of the introduction of high class dairy cattle, four hundred thousand pounds of the best grade of milk is now produced. Formerly, milk was not very extensively used, the general public having a prejudice against using such a filthy pabulum. At present the supply, although it is increasing rapidly in amount, cannot keep pace with the demand. Practically all the milk is pasteurized. Herds are regularly tested with tuberculin and all infected animals are segregated from the herds. The Panaman government now has under consideration the appropriation of $10,000 for the purchase and destruction of infected cattle. It is now forbidden to sell bulk milk, only milk in approved bottles and well iced being permitted to be sold. The production of safe milk in the tropics has always been considered an exceedingly difficult matter. Many tropical places are almost wholly without fresh milk of any sort. The production of an adequate, safe milk supply at Panama is therefore another triumph for American sanitation.

ALASTRIM IN JAMAICA.

Reports from the island of Jamaica indicate that the epidemic of alastrim has assumed endemic proportions. Since midsummer, 1920, the island had never been free of the disease, and during the week ended October 20, 1923, twenty-three new cases were reported. None of these occurred in Kingston and visitors need have no fear in visiting that city, in fact, anyone who is well vaccinated against smallpox need have no fear of the disease and anyone who is foolish enough to travel without having first been vaccinated deserves to have it.

ANTITYPHOID INOCULATION IN TRINIDAD.

The health authorities of the island of Trinidad have begun a campaign of free antityphoid inoculation which is meeting with general acceptance.

MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE.

The 203d meeting of the Medical Association was held at Santo Tomas Hospital on November 16, 1923, and the following program presented: Occupational Therapy in the Treatment of the Insane, by Capt. G. E. Hesner, M. C., U. S. A.; Eventration of the Diaphragm, by Lt. Col. Roger Brooke; Pituitary Gland, by Dr. D. G. Sampson; Observations on the Chemistry of the Blood in Epilepsy, by Dr. D. G. Sampson and Mr. J. E. Jacob; Presentation of Cases by Dr. H, J. Hayes, as follows: Progressive muscular atrophy, pellagra, with skin lesions, and cerebrospinal syphilis.

FREE VISUAL EXAMINATIONS FOR CHILDREN OF PANAMA CITY.

The Rotary Club of Panama City has inaugurated a campaign for providing without cost suitable glasses for children who are unable to purchase them. Through the kindness of a physician, who is a member of the club, and an optical manufacturer, also a member of the club, examinations will be made free of charge and glasses will be furnished at their cost to the club.

RESEARCH STATION ON BARRO COLORADO ISLAND.

On April 16, 1923, the Governor of the Panama Canal set aside Barro Colorado Island in Gatun Lake as a Natural Park where the regional flora and fauna may be propagated and studied and a number of scientists have already availed themselves of the opportunities thus afforded of conducting research in this favorable situation. The first reconnaissance of the island was made by Dr. William Morton Wheeler, of Harvard University; Mr. James Zetek, of the United States Department of Agriculture, and Dr. Richard Strong, dean of the School of Tropical Medicine at Harvard University. As a result of their studies a number of new and interesting species of termites and ants were discovered and much light was thrown on their life habits. Later Dr. Hitchcock, Dr. Maxon, and Dr. Cook, of the United States Department of Agriculture and the United States National Museum, visited the island and made several valuable botanical finds, and Mr. R. C. Shannon, of the United States Bureau of Entomology, built a shelter there and lived in it for two months while he studied bloodsucking flies. Dr. Frank E. Lutz, associate curator of the American Museum of Natural History, is now on the island conducting a series of observations on the habits and species of stingless bees, a very destructive pest of citrus plants. Dr. W. C. Allee, associate professor of zoology at the University of Chicago, will come in January under a grant from the National Academy of Sciences, to work out important soil and air problems on the island. Dr. Thomas Barbour, a noted herpetologist and zoologist of the Museum of Comparative Zoology at Harvard, will soon come to the Isthmus for the purpose of directing the erection of a number of screened buildings which the National Research Council will build on the island. The geographical position of the Isthmus makes this research station of tropical biology one of the most important in the world and it is expected that students and scientists from many portions of the globe will come to study the plants and animals there.

HEALTH CONDITIONS IN VALPARAISO, CHILE.

Press reports indicate that Valparaiso is again in the grip of epidemics of smallpox and typhus fever. On October 18, 1923, the following movement of patients was reported in the lazaretto Salvador of Valparaiso:

	Smallpox.	*Typhus.*
Entered	0	8
Died	9	3
Discharged	0	3
In bed	3	89
Convalescent	3	23

According to the official census of January 1, 1923, the population of Valparaiso was 188,875.

OCTOBER REPORT OF THE COLON FREE CLINIC.

The Cristobal Woman's Club is still continuing the Colon Free Clinic and Soup Kitchen. Dr. J. L. Byrd, the health officer of Colon, reports that during the month of October the following work was done:

Medical cases treated	219
Surgical cases treated	523
Eye, ear, nose and throat cases treated	169
Babies treated	108
Prenatal cases treated	13
Dental cases treated	23
Vaccinations performed	89
Specimens to laboratory	14
Wassermann reactions performed	5
Diphtheria antitoxin given	3

GENEVA LETTER

(*From our own correspondent*)

Geneva, *September 15, 1923.*

ENTAMEBA AND SPIROCHETA IN PYORRHEA.

(*Concluded from page* 649)

GIEMSA PROCEDURE.

For the slow Giemsa procedure—which Zouraboff considers far the best of any—the preparations were left for twenty-four hours in a 1:20 Giemsa solution in melted snow, after which they were washed in running water and examined under oil immersion.

Leishman's method also gave good results. The preparations, air dried and treated with methyl alcohol, were covered with a few drops of Leishman's solution which was allowed to act for thirty minutes and then a double amount of melted snow was allowed to act on it for five minutes. This very rapid method is, as far as distinct staining is concerned, about equal to Giemsa. It gives rise to precipitates readily, but these can be avoided by agitating the preparation during the five minute staining.

OTHER STAINING METHODS.

Wiener's method was employed for staining the ameba of dysentery and, with some changes, gave rather good results for the staining of entameba gingivalis. The following technic was used: The preparation fixed with methyl alcohol was covered with a one per cent. solution of iodine for five minutes and then washed in water; stained with Löffler's blue for ten minutes, washed in water and lastly plunged in an alcohol solution of eosin diluted 1/4 with melted snow, for five minutes. This technic gave rise to precipitates.

Another very practical method for rapid research, especially from its simplicity and rapidity, is Manson's blue. After fixation with methyl alcohol the preparations were treated with Manson's solution, one drop diluted with four c. c. melted snow, for thirty seconds.

When stained with Giemsa, the ameba appeared as a large round or oval cell with distinct festooned contours. It varied in size between 10, 18, 20 and 28 micron. The ectoplasm of the organism, distinctly differentiated, stained a homogenous pale blue; the granular endoplasm could be distinguished especially by its round or oval digestive vacuole which varied in size according to the state of contraction of the ameba, so that in some preparations they were large and few; in others very small and very numerous. Violet stained bacteria could be distinctly seen within the vacuole, as well as bits of nuclei of leucocytes and salivary corpuscles. The nucleus stood out well, stained dark rose to red, assuming the annular shape and often the characteristic horseshoe form. Occasionally it was bilobate. In one instance it was found that the chromatin of the nucleus was distinctly separated into four parts or lobes. In the centre it presented a lighter corpuscle which was the nucleolus.

Wiener's method stained the protoplasm azure and the vacuole pale pink; the nucleus was darker pink. With Giemsa the ectoplasm and endoplasm could not always be so distinctly differentiated.

Manson's blue distinctly differentiated the ectoplasm in dark blue, the endoplasm in lighter blue.

DISTINGUISHING FEATURES.

It is important to note that each time several ameba were found in one spot they were invariably small, so that Zouraboff concludes that these were young organisms which had just been formed by division. In one preparation taken from a subject with the history of familial pyorrhea at a single spot eight ameba of equal size were seen. The same preparation also showed four small ameba closely tucked together. Their nuclei were vividly stained, the chromatic substance being very distinct. In another case of pyorrhea the preparation showed a beautiful group of three young ameba close together, while the protoplasm of two was in continuity.

Some observers—Newlin, Goodey and Wellings—have maintained that the bacteria and bits of nuclei seen within the vacuole were simply superposed on the ameba and that consequently this parasite could only feed by osmosis. Now, in Zouraboff's preparations, it was distinctly seen that some bacteria and nuclei were superimposed on the ameba while others were just as distinctly seen within the vacuola, both having a different focal distance so that it was impossible to be mistaken. And this observer concludes that far from feeding by osmosis, entameba gingivalis digests bacteria, salivary corpuscles and leucocytic nuclei in their vacuola. Red blood corpuscles were never found in the vacuola.

Newlin and Craig have stated that this ameba can give rise to cysts, but without denying that they can do so, Zouraboff states that he never found any in his preparations. The total number of subjects examined was ninety-three of both sexes, ranging in years from two to sixty-one. Of these ninety-three, fifty-one had pyorrhea and gingivitis. In these fifty-one cases the ameba was present in twenty-five—49 per cent. They varied in number and even in the different preparations made from the same subject. Thus, in four preparations from the same mouth and taken from the same spot, only one contained the ameba.

AGE OF PATIENT NO FACTOR.

In almost all the cases, besides the ameba, the spirocheta dentium was present as well. In nine cases of pyorrhea and gingivitis the spirocheta was present, the ameba absent. The frequency of the ameba in pyorrhea does not appear to be in any way related to the age of the patient, because it was found as frequently at the age of twenty years as in individuals near the sixties.

The ameba was present in 61.5 per cent. of cases of pyorrhea in the male and in 48 per cent. of cases in the female, so that the difference is not great. The ameba is not more common in mouths with dental caries than in those containing only healthy teeth. On the other hand, preparations made from material removed from the neck of a tooth always contained more than that removed from the interior of a carious tooth. Of forty-two subjects with healthy gums ameba were found in only one. Upon several occasions spirocheta were present in preparations derived from healthy mouths, but they were very few in number and never formed clusters such as are seen in cases of pyorrhea and gingivitis.

In one case the action of emetine hydrochlorate on the entameba gingivalis was studied. The patient, a male of twenty years, had lived in the colonies and contracted amebic dysentery. He also suffered from gingivitis and specimens from his mouth contained some very fine and numerous ameba associated with the spirocheta dentium. The patient had undergone a treatment with emetine at the dose of three centigrams twice daily for eight consecutive days as treatment for the dysentery. The material was taken from the mouth at the end of treatment and the preparations were free from ameba and only the spirocha from the gingivitis could be found.

Book Reviews

SKIN DISEASE.

Diseases of the Skin. By Frank Crozer Knowles, M.D. Second Edition. Philadelphia and New York: Lea & Febiger, 1923.

Diseases of the Skin. By Richard L. Sutton, M.D., LL.D. Fifth Edition. Revised and Enlarged. St. Louis: C. V. Mosby Co., 1923.

A most convenient textbook on dermatology. Most important is the author's concept of the human organism as an entity. His approach works from the organism with a regard for the integument as a portion. Of value to the practitioner are the diagnostic tables. Radium and x ray therapeutic methods have been rewritten to conform to more modern methods and findings. Ringworm has been found to be a causative factor in many obscure skin diseases and this subject has been handled from the point of view of the latest discoveries. The book is not as cumbersome as many other textbooks and for practical purposes should meet the requirements of the busy physician.

* * *

The fifth edition of Sutton's comprehensive textbook is of great value as the recent literature on the subject has been carefully gone over and the most essential references included. The illustrations which in a book on dermatology should be of a high quality are all that could be demanded. New headings have been given to many skin affections due to the factors pertaining to them which have hitherto remained obscure. Much of the contributed material from outside sources has come from the younger American dermatologists who are rapidly forging to the front as investigators. The fifth edition of this important book should be warmly welcomed.

THE HEART

The Heart, Its Physiology, Pathology and Clinical Aspects. By Selian Neuhof, M.D. Philadelphia: P. Blakiston's Sons & Company. 1923.

The aim of this volume is to present the entire subject of cardiac and cardiovascular disturbances and diseases in a clear, well balanced manner preeminently from the clinician's viewpoint. The first few chapters deal with embryology, anatomy and physiology. The chapter on physiology is limited to a consideration of impulse formation and conduction, and to the cardiac innervation. Inadequate attention is given in another chapter to the important subject of cardiodynamics and to the work of men like Straub, Starling, Henderson and Wiggers. A separate chapter is devoted to a superficial discussion of cardiac pathology. In the opinion of the reviewer it would have been wiser to discuss the pathology of each important affection of the heart in connection with the symptomatology. Such an arrangement helps the student to formulate clearer concepts of disease. Similarly, the clinical chapter on congenital heart disease, which is too short, could well have been combined with the anatomical one. The sections on the arrhythmias, and on the graphic methods employed in the study of heart disease, are fairly complete.

The author states on page 190 that pulsus paradoxus has been regarded as characteristic of pericarditis with effusion. As a matter of fact it has been associated with adhesive pericarditis. The discussion of myocarditis is unsatisfactory. The true infections of the myocardium are not clearly differentiated from the degenerative lesions. Thus the author speaks of myocarditis in pulmonary emphysema as the cause of the cardiac symptoms.

The last 170 pages of the book are devoted to cardiovascular clinics, case reports of a wide variety of conditions. They are out of place in a book of this nature. Brief references in the text to illustrate cases that are particularly illuminating would be of real value.

As a whole Dr. Neuhof's book, while it contains many facts and observations, is not well planned. The necessary correlation of anatomy, physiology, pathology and the clinic is not achieved. The references to the literature are not always well chosen. The illustrations, although numerous, are not well reproduced.

LEISHMANIASIS

Leishmaniasis y Blastomicosis en America. Por El Dr. Edmundo Escomel. Lima: Polvos Azules, 1922.

For those who read Spanish this little monograph affords interesting information concerning the occurrence, the lesions, the diagnosis and the treatment of leishmaniasis and blastomycosis, as it is found in South America. Apparently both diseases are more frequent there than has hitherto been thought. A useful table for the differential diagnosis of the two diseases is given, but it is pointed out that they may both occur in the same case. The pictures of patients suffering from blastomycosis show a much more serious type of disease than is usually seen in the United States.

GENERAL PRACTICE

An Index to General Practice. By A. Campbell Stark, M.B., B.S. (Lond.), L.S.A. (Eng.). New York: William Wood and Company, 1923.

This interesting and useful little volume of less than two hundred pages was written solely from the point of view of the general practitioner, and the matter under each heading, according to the author's preface, is to be considered as a syllabus of the subject rather than an attempt to instruct. The volume aims to benefit the general practitioner rather than the specialist. The author emphasizes the fact that in England, at least, writers of textbooks, makers of surgical instruments, and others who cater to the needs of the medical profession, have little to offer to the general practitioner, so that he is left to work out his own salvation.

The author attempts to make an exception to this general rule, and it must be admitted he has succeeded in writing a work that must have a certain appeal to the man in general practice. It is difficult to agree with much that is in the book, but in the main the teachings are conservative and useful. There seems to be a marked disproportion in the amount of space allotted to the various subjects, as may be judged by the three and one half pages devoted to alcoholism, the first subject considered, and the little over two pages given to the last subject venereal diseases. Gonorrhea gets less than eight lines, including the comment that "the following books will be found to contain as much information as he (the practitioner) is likely to need." The key to this interesting little work is found in this bit of philosophy: "It is better to be right nine times out of ten than to make a brilliant diagnosis in the tenth case." All of which might be submitted to some of our brilliant internists for serious consideration.

HYGIENE

Hygienisches Praktikum. Von Dr. Med. Paul Uhlenhuth. Zweite, neubearbeitete Auflage. Mit 86 Abbildungen im Text und einer Tafel. Berlin und Wien: Urban & Schwarzenberg, 1923.

This is an eminently practical handbook on hygiene for the use of medical students, those preparing for the position of sanitary inspector, and as a guide in hygienic laboratories. The various tests taught in the courses on practical hygiene are described in minute detail. In this edition many of the shortcomings of the former edition have been overcome, and the chapter on light and illumination has been completely rewritten. The subjects discussed are soil, water, the examination of foods in general, milk, butter and food fats, meat and meat products, flour alcoholic beverages, adulterations of foods, and commercial products, clothing, air and its movement, and light and illumination.

SURGEON GENERAL'S REPORT

The Medical Department of the United States Army in the World War. Volume I. The Surgeon General's Office. Prepared under the Direction of Maj. Gen. M. W. Ireland, M.D., Surgeon General of the Army, by Col. Charles Lynch, M.C., Lieut. Col. Frank W. Weed, M.C., Loy McAfee, A.M., M.D. Washington: Government Printing Office, 1923.

This volume deals with a complete report of the work as carried out by the Surgeon General's office and constitutes part of a series of reports on the work done by the Medical Department of the United States Army in the World War. The evolution of the Medical Department from the earliest times, both in the rest of the world and in this country, down to the time of the World War and of the Red Cross Medical Department units, are briefly reviewed. The first section details the relationship of the Medical Department within the War Department. The second section describes the organization and administration of the Surgeon General's office and its various divisions. The third section takes up the work of the various voluntary aids, such as the American Red Cross, the Council of National Defense, the National Research Council, the American Medical Association, and the Commission of Training Camp Activities. The appendix contains the orders, regulations, and other instructions governing the Medical Department during the World War, occupying about half the volume. The latter is the most important part of the report to the medical world, as it shows not only the development and organization of the various medical outfits, but also shows the progress of medical and surgical care of the army and the necessary prophylactic measures.

DIABETES

Die Hausärztliche Behandlung der Zuckerkrankheit. Erweiterte Bearbeitung eines Vortrags gehalten am 13. Dezember 1922 in der Berliner Medizinische Gesellschaft. Von Professor Dr. Carl von Noorden, Frankfurt a. Main. Berlin: Verlag von Julius Springer, 1923.

This monograph covers the treatment of diabetes by the general practitioner. The fate of the diabetic patient depends to a very great extent upon his mode of life. The author discusses the prophylaxis, the early recognition of the disease, the early and the late signs of diabetes, the general duty of the family physician and the special points of interest in the treatment, such as various dietaries, the starvation treatment, the avoidance of overfeeding, muscular work, the use of spring waters and drugs, the clinical treatment and coma. Not much is said about insulin, as at the time of this address very little was definitely known about it. With this exception, nothing but praise can be said regarding this article by a master on the subject of diabetes. The article is short and to the point.

HYDROTHERAPY

Prieger-Krebs Grundriss Der Hydrotherapie. Zweite Auflage Bearbeitet von Dr. Walter Krebs. Bonn: A. Marcus & E. Weber's Verlag, 1923.

Hydrotherapy has assumed quite an important place in therapeutics and is applicable in a great many diseases. The various methods of applying hydrotherapy in disease are discussed in great detail. In addition, the various types of physical therapy and their indications as adjunct treatment are also described. The first part of the book deals with the effect of hydrotherapy on the body, including the effect on the temperature, metabolism, the blood, the secretions and excretions, the musculature and on the nervous, the respiratory and circulatory systems. The second part deals with the technic, the direct and mediate effects of the various methods of applying hydrotherapy. The third part deals with the use of hydrotherapy in the different diseases. This little book may be highly recommended as a guide to hydrotherapeutic measures.

BACTERIOLOGY

Practical Bacteriology, Blood Work and Animal Parasitology. By E. R. Stitt, A. B., Ph. G., Sc. D. LL. D. P. Blakiston's Son and Co., Philadelphia, Pa.

The fact that this volume is now in its seventh edition is sufficient evidence as to its popularity. It has been necessary to incorporate considerable new matter since the appearance of the sixth edition two years ago, so that 132 new pages have been added, which brings the book well up to date. Even such recently published work as that of Guthrie and Huck on the existence of more than four isoagglutinin groups in human blood is referred to. In connection with blood grouping, Stitt has abandoned the classification of Moss, which he used in former editions, and on the recommendations of the special committee representing the American Association of Immunologists, the Society of American Bacteriologists, and the Association of Pathologists and Bacteriologists, has adopted the Jansky classification. Kolmer's modification of the Wassermann technic is described, as are the flocculation tests for syphilis, that of Kahn, Sachs and Georgi and Meinicke's third modification of the latter method. The appendix contains an interesting section on the problems of nutrition in health and disease, in which the vitamines and food deficiency diseases are described. This volume can be heartily recommended as an excellent laboratory guide, and as an exceedingly useful book of reference.

THE CLINICAL LABORATORY

Clinical Laboratory Methods. By Russell Landram Haden, M.A., M.D. St. Louis: C. V. Mosby Company, 1923.

This volume is the outgrowth of a collection of notebooks used in the development and standardization of the work in a hospital laboratory. For each procedure only one method is given, and Haden states in the preface that he has intentionally avoided the interpretation of results, as the book is in no sense a textbook. Hence its sphere of usefulness is considerably restricted. However, the methods used are clearly and simply described in most cases, though in a few instances one might choose rather more elaborate technic, gone into more fully. For example, the determination of the blood group of patient and donor for transfusion tests is one of the most important examinations that a laboratory makes. For this, Haden describes a macroscopic method. Most careful serologists and clinicians would feel safer if such tests were done by microscopic examination. The section on histological technic comprises some eight and a quarter pages, and while it includes the technic for staining mitochondria, it omits that of Warthin and Starry for the demonstration of spirochetes in tissues. A pathological laboratory is probably called upon as often to perform one examination as the other.

CHEMISTRY

Elementary Chemical Calculations. By Martin Meyer, Ph.D. New York: Oxford Book Company, 1923.

As its name would indicate, this book presents the fundamental mathematical calculations of the science. It consists of thirteen chapters treating individual types of problems and concludes with a final review of the whole. The appendix includes tables of atomic weights, vapor tension of water, Centigrade-Fahrenheit conversion, and convenient four place logarithms.

The arrangement of the material is novel and attractive. Each chapter opens with an introductory exposition of the principles involved, and this is followed by one or more typical examples fully solved. The chapters close with carefully graded lists of problems for the student. The information is highly condensed and includes practically nothing that is not absolutely essential. This makes it slightly difficult to read, but is more than compensated by the saving in time for the reader or student. The author has accomplished his avowed purpose of presenting a book which will accompany any standard textbook of chemistry, and without repetition of the latter, give the pupil a thorough knowledge of chemical arithmetic.

The volume can therefore be recommended as a good textbook and furnishes a handy little reference work for others than students. It is of high school or first year college grade, though probably more fittingly the latter.

THE CERVICOTHORACIC SYMPATHETIC

Le Sympathetique cervicothoracie. Par Docteur Thomas Jonnesco, professeur dans le Faculté de Bucharest. Paris: Masson et Cie, 1923.

Jonnesco's first operations on the cervical sympathetic for epilepsy and exophthalmic goitre date back to 1896, and at that time were very limited in extent. Then, after extensive study of the topographical anatomy, histology and animal experiments, he developed the surgery of the cervical sympathetic as no other surgeon has done. Subtotal resection, as he first resorted to, acted only on the encephalic vasomotor tracts, hence the inferior cervical ganglion was comprised in this resection, therefore including the first thoracic ganglion, with the result that total resection of the cervicothoracic sympathetic is now done. In addition to the treatment of epilepsy and exophthalmic goitre, this resection is now done for facial neuralgia, glaucoma, essential migraine and angina pectoris.

This volume in folio presents the work of a quarter of a century, and although the reviewer is fully aware that Jonnesco's work is not appreciated in the United States, it is nevertheless quite worthy of study by American surgeons. The book is illustrated with thirty-four figures and ten colored plates of great perfection. A very complete bibliography is appended.

HUXLEY

Essays of a Biologist. By Julian Huxley. New York: Alfred A. Knopf, 1923.

In this series of essays varied in the handling from the most serious to fantasy sketches, Huxley attempts to show the workings of biological phenomena in their relationship to evolution and to affairs of man. He reaches back over stretches of time and pleads for a broader concept of man's values of man. Of particular interest is his chapter on the biology of sex, in which he weaves in the most modern psychological findings. The book should stimulate many to new ideas and will serve to reaffirm others in certain stands they have taken.

EXPERIMENTAL PSYCHOLOGY

Abhandlungen und Monographien aus dem Gebiete der Biologie und Medizin. Herausgegeben von Alexander Lipschütz, Dorpat. Drittes Heft: Jonentheorie der Reizing. Von Dr. P. Lasareff. Mit 11 Abbildungen. Bern und Leipzig: Verlag Ernst Bircher Aktiengesellschaft, 1923. Pp. ix-51.

It has been shown that the electrically loaded atoms, the ions, play an important part in the phenomena of stimulation. Changes in the concentrations of the ions in the living tissue result under the influence of stimulation. If this concentration of the ions has exceeded a certain threshold value, changes in the surface tension of the atoms of the albumin result, and consequently also changes in the condition of the entire tissue (precipitation). The author endeavors to apply strictly physicomathematical methods to the investigation of psychic phenomena. The first two chapters deal with the basic principles of stimulative processes, and the stimulation resulting from the electric current. This principle is applied to the optic, auditory and gustatory sensations. This work is based on the author's experimental investigations. The remaining chapters deal with the dissemination of the stimulation, the geometrical arrangement of the distances between the neurons and the reflexes, and the activity of the centres. This brochure is of great value to those interested in the physiology of experimental psychology. A knowledge of the higher mathematics by the reader is assumed.

Medicoliterary Notes.

The Committee on Mental Hygiene of the New York State Charities Aid Association has issued a directory of the chief mental clinics maintained by general hospitals and public health agencies in the Manhattan district of New York City . . . It contains not only the location of the clinics, but such additional information as hours at which they are held, names of directors, scope, and charges, if any. —*Mental Hygiene Bulletin.*

Both France and England now require medical tests for chauffeurs. If an unfit driver insists upon continuing his employment, the physician consulted must either warn the chauffeur's employer or be held responsible for a fatal accident at a later date.

* * *

Probably only a few persons know or remember today that the Yosemite Valley was discovered and named in 1851 by Dr. Lafayette Houghton Bunnell, who was born in Rochester, N. Y., in 1824, and who later resided and practiced medicine in the West.

Practical Therapeutics

THE TREATMENT OF DISEASES OF THE SKIN BY X RAY*

By Joseph Brumberg, M. D.,
Buffalo,
Assistant in Dermatology, University of Buffalo.

In treating diseases of the skin with x rays, unfiltered rays are used, filtered radiation being employed in but few cases. These unfiltered rays are measured, or their quantity calculated, and exact doses are given for various conditions. These formulæ and doses apply only to unfiltered radiation, and only when the rays have been given off from a standard type Coolidge tube, activated by an interrupterless transformer. The small bedside and fluoroscopic x ray units, which use a radiator type Coolidge tube, should not be used for treatment.

For computing the amount of radiation put out by a tube while in use, a formula has been worked out, the factors of which are the milliamperage and voltage of the current producing the rays, the distance of the tube from the skin area treated, and the time the skin is exposed to the radiation. If a tube is activated with three ma. and 700,000 volts (six inch spark gap), and an area of skin eight inches from the centre of the tube exposed for two minutes to this radiation, with no filter interposed between tube and skin, then the skin area so treated will have absorbed the largest amount of radiation that will not produce a reaction, and this is called the skin toleration dose, or one skin unit. One skin unit may be repeated to the same area every four weeks. One half this amount, or one half skin unit, can be repeated every two weeks; three eighths of the skin unit may be repeated every ten days; one quarter skin unit may be repeated every week, and one eighth skin unit twice weekly.

It is important to know just what harm is done to the skin by doses of x rays exceeding the skin toleration dose. Any reaction of the skin to x rays is radiodermatitis. First degree radiodermatitis is an erythema only, redness of the skin with burning and itching, selfcuring and not of any seriousness except when it is provoked on the face, for on the face even a first degree reaction may be followed after a time by slight atrophy of the skin, pigmentation and telangiectasis. In treating some serious dermatoses, particularly epithelioma, we use an amount of radiation greater than one skin unit, and deliberately face the prospect of producing a mild first degree reaction.

Second degree radiodermatitis follows the exposure of the skin to much larger doses. This reaction is marked by erythema, edema and vesiculation, accompanied by marked burning and pain, tends to spread to other skin areas, and requires several months to cure. Third degree radiodermatitis follows very massive doses of radiation and is marked by the conditions mentioned above plus ulceration or gangrene of the skin, excruciating pain and a chronic course; and when after many months healing takes place, there may follow as sequelæ on the damaged skin the development of keratosis and epithelioma. One should never, under any circumstances, knowingly give an amount of radiation that will produce a second or third degree radiodermatitis.

That this system of estimating x ray doses and the skin toleration to x rays can be depended on, is attested to by all dermatologists, and hundreds of thousands of patients have been so treated without danger. It is agreed, now, that idiosyncrasy to x rays does not exist, idiosyncrasy meaning here, that in certain persons a small amount of x rays will produce a violent reaction. Invariably, an unexpected reaction can be accounted for as due to error by physician or patient. The physician may be at fault through using faulty apparatus, in erroneous calculation of doses, or in repeating full doses before the necessary time limit has elapsed. Or the patient may be responsible for the reaction by interfering with instructions given to keep irritants off the skin. Some accidents of radiodermatitis are due to the simultaneous use on the skin of full doses of x ray and irritating chemicals like iodine, chrysarobin and others, and it is necessary before treating the skin with large doses of x rays to inquire whether irritating applications have been made within a week previously, and to warn against using such applications for several weeks after the treatment. It seems probable that the cases reported as idiosyncrasy, where the physician can find no apparent cause for the reaction, are really due to some ill advised interference by the patient. For example, a man with sycosis vulgaris, to whose face one half unit, a perfectly safe dose, was given, presented a week later a mild first degree reaction, an erythema. On further questioning, he told what he had at first concealed, that he had applied to his face right along a strong alcoholic solution of bichloride of mercury. Another instance: A patient was treated for epithelioma and a massive dose of x rays was given, from which not more than a mild erythema should have resulted. Two weeks later this patient returned with a violent second degree radiodermatitis, and said that, in spite of my cautioning her, neighbors had induced her to apply very strong solutions of lysol to the irradiated area. In both these cases the amount of x rays used was within safe limits, but the patient's own interference produced the reactions.

BIOLOGICAL ACTION OF X RAYS.

The biological action of x rays as used in dermatology, depends on their ability to destroy abnormal cells, or at least to limit their activity and to prevent their reproduction. The abnormal cells infiltrating the skin in various dermatoses are destroyed by amounts of radiation that will not affect normal tissue cells, and the clearing of skin eruptions under x ray treatment is due to this selective action, by which the pathological process is made to disappear and normal skin is spared.

This explanation of the biological action of the rays can be systematized to cover the various types of dermatoses requiring different methods of using the rays. Acute and chronic simple inflammatory diseases of the skin are characterized by infiltration of the derma with small round cells—lymphocytes. These cells are the least resistant and are influenced by small amounts of radiation. Such diseases are treated with one eighth or one quarter units, repeated every three or seven days respectively. The more stubborn inflammatory dermatoses show infiltration with fibroblasts in addition to lymphocytes, and require slightly larger amounts of radiation, three eighths unit repeated every ten days. Granulomata of the skin show infiltration with giant cells, plasma cells and epithelioidal cells, and to affect these one half to three quarter unit doses are required, this amount being repeated after two or three weeks. Neoplasms of the skin, epithelioma, and sarcoma, whose characteristic is overgrowth and infiltration with their particular malignant cells, the most resistant of all pathological cells, call for the use of massive exposures to x rays, from one and one half to two skin units. Fortunately, normal tissue cells are more resistant to radiation than any of these, and even when doses of two units are given for malignant disease of the skin, the normal tissue will recover quickly and satisfactorily. With the use of fractions of one skin unit, as employed for most dermatoses, the skin is never in any danger.

---

*Read before the Buffalo Academy of Medicine, October 11, 1922

It is a much debated question whether x rays are antiseptic. Experimentally, bacteria in culture, in a test tube, are not killed by x rays. However, this agent does cure many dermatoses which are due to microorganisms, both bacteria and fungi. Either the x rays so change the tissue that microorganisms find conditions unfavorable for their growth, or there is elaborated in the skin and of the skin some new and more subtle influence which is antiseptic. There is some evidence that the second possibility may be a fact, and it is supposed that as a result of absorption of x rays by the skin, a new and different radiation is elaborated in the cells of the skin. If this does occur, the new radiation is not similar to x ray, but an electronic ray similar to the beta rays of radium, and this is supposed to be antiseptic.

ECZEMA, PSORIASIS, ETC.

In the large group of inflammatory dermatoses, the x ray is the method of choice. This group includes such common conditions as eczema, seborrheal dermatitis, dermatitis venenata, psoriasis and lichen planus. These diseases are marked pathologically, as to the epidermis, by parakeratosis, with spongiosis and vesiculation in moist conditions, and acanthosis in dry conditions; and in the corium by infiltration with lymphocytes and sometimes fibroblasts. This process is readily checked and made to disappear by small doses of radiation, the average being one quarter unit repeated weekly. From three to ten such exposures, varying with particular conditions, are required to eradicate the eruption. One of the first results obtained is relief from the itching or burning which accompanies many of these dermatoses. These symptoms are greatly relieved at the first exposure and leave after two or three exposures. Soon after treatment is started the vesiculation and oozing, or scaling, in the various types, is checked, infiltration of the skin becomes less and less, until the skin is restored to its normal condition.

Often these inflammatory diseases cover extensive areas, sometimes the entire body. It is safer not to treat more than one third of the body surface at one sitting. The usual practice is to expose on one day the face, scalp, and upper extremities, two days later the trunk, and two days after that the lower extremities, so that the entire body is treated in one week. In succeeding weeks the same division of exposures is repeated. In this way are avoided any toxemia and changes in blood cells which might follow the exposure of too great a body area to radiation at one time.

The advantage of x ray therapy in these conditions over older methods using external applications is that it is more dependable and more generally efficient. In addition, the relief from itching and burning is more quickly secured, and the duration of the eruption is shortened. Patients invariably prefer x ray treatment because it is quickly efficient and in addition, the patient does not have the inconvenience of applying medications, nor the annoyance of going about so anointed.

In eczema, seborrheal dermatitis, dermatitis venenata and lichen planus a permanent and lasting cure can be obtained. In psoriasis, x rays will quickly remove the eruption, but cannot prevent its recurrence at some future time; though it seems that when treated by x rays the eruption does not recur until after a longer period has elapsed than after treatment by external applications. Patients who have been treated for psoriasis by both methods are unanimous in prefering the x ray, because it is cleaner and more efficient than the application of reducing agents and there is no danger of a dermatitis which frequently follows the use of chrysarobin.

ACNE VULGARIS.

As types of dermatoses due entirely, or in part, to pyogenic organisms, acne vulgaris and sycosis vulgaris are well treated by x rays. For acne vulgaris, the x ray is better than any other treatment known. In most cases, but not in all, the eruption can be entirely removed, and in the cases which can not be entirely freed from the eruption, a marked improvement can be secured. About five per cent. of the apparently cured cases will relapse, but the relapse is not severe and responds to a few additional exposures. Under x ray exposures the comedones, papules and pustules disappear, the hyperactive sebaceous glands which furnish the soil for the acne bacillus are checked, the follicular openings are less patent, and the thick heavy oily skin which is the background for acne vulgaris is changed to a skin more nearly normal in those respects.

Pathologically, acne vulgaris is more than a simple inflammation. There is a follicular and perifollicular infiltration with lymphocytes, and through bacterial action a small perifollicular abscess is developed. The changes in the corium are more than a simple inflammation, for surrounding the small purulent focus is a dense mass of granulomatous cells in which are found plasma cells, multinucleated cells or chorioplaques, and connective tissue spindles. From this picture it would be predicted that half unit doses would be most effective, and so they are, and in severe nodular forms of acne that dose is used; but because acne is treated most often on the face, and treatment continued over a period of several months, it is safer to use average doses of one quarter unit of x rays, repeated every seven days. A permanent cure is always tried for, and from ten to fifteen such exposures given. At the same time any hygienic or dietetic changes, indicated by the patient's condition, are instituted.

So effective is x ray treatment of acne vulgaris that there is a tendency to overuse the method, by treating persons who have only a stray papule or two on the face. There is no danger or harm in so treating, but it is not necessary, as these very mild eruptions can be treated satisfactorily by hygienic and dietetic measures alone, or with the very simplest medication. But if the eruption is at all stubborn, or extensive, and especially if pustules or nodules appear with their danger of scarring, x rays are at once indicated.

Sycosis vulgaris, a similar pyogenic infection of hair follicles, presents the same indications as acne vulgaris and is similarly treated. Occasionally a case presents itself which will not yield to fractional doses, but requires the application of sufficient rays to produce a temporary falling of the hairs in the affected areas, after which the disease is found to be cured. This method of temporary depilation by x ray will be discussed under ringworm of the scalp. Before x rays were used, sycosis vulgaris was an exceedingly stubborn and often incurable condition, and x rays have been a blessing to those so infected.

RINGWORM OF THE SCALP.

The dermatological conditions due to fungus growth furnish cases well treated by x rays. Ringworm of the smooth skin is not usually irradiated, as the usual antiseptic treatment is sufficiently effective. Ringworm of the nails, as stubborn a condition as any we meet, will respond to the persistent use of x rays, and excellent cures can be had by raying cases of actinomycosis, blastomycosis and sporotrichosis.

The greatest triumph for x ray therapy in this group of fungus infection is in the cure of ringworm and favus of the scalp. These dermatoses, chronic and readily communicable, presented a most difficult problem before x rays were used. Treatment was conducted by a long painful course of pulling out hairs and rubbing in some strong antiseptic, a laborious and disagreeable treatment to the patient and the attendants, so irksome that most patients would never persist in the treatment and remain uncured and infect others. This painful and tedious method would be persisted in for from six months to two years, during which time the child, for these are children's diseases, could not attend public school.

Today we cure ringworm and favus of the scalp at one sitting, and after six weeks the child returns to school. The method is to produce a temporary alopecia of the entire scalp. The fungus causing these scalp diseases lives almost entirely on the hairs, and to a very small extent, if any, in the epithelium lining the follicles. If, then, all the hairs, with their burden of organisms, are removed at one time, then the small remainder of the process, if any remain, is readily terminated by any mild antiseptic treatment. The amount of x rays used is exactly one skin unit. That amount on a hairy part produces a temporary epilation, with the assurance that the hairs will regrow. The margin of safety between this dose and the erythema dose, which would produce a hopeless, permanent alopecia, is none too wide, not much over thirty-three per cent., but this is ample in the hands of an experienced worker, and the method is today universally employed.

The technic is this: The child's scalp must not have been irritated by strong iodine or chrysarobin ointments for two weeks before treatment, nor after; at treatment the scalp must be free from scales and crusts, and the hair clipped very close to the scalp. The rays are applied at five points: the vertex, the frontal and occipital regions in the midline, and the right and left temporal regions, all of these equidistant from each other so the overlapping of rays will be the same in all areas, and the irregularly shaped scalp uniformly irradiated. One skin unit is given at each point and the rays allowed to spread widely and overlap. After treatment, the scalp is washed daily, and at the end of two weeks, when the hairs begin to loosen and fall, they are carefully removed. The third week finds the child's head completely bald, and at this time a two per cent. ammoniated mercury ointment is rubbed into the scalp daily. After remaining bald for an average of six weeks, the hairs start to regrow, the new growth of hairs is of the same texture and strength as before, and when regrowth is completed, the scalp is found free from infection.

The treatment of ringworm and favus of the bearded portion of the face in men is by the same method of temporary x ray depilation.

HYPERTRICHOSIS.

As soon as it was known that x rays would depilate, the ray was used in attempts to cure hypertrichosis, particularly superfluous hairs on the face of women. Unfortunately the rays cannot be so used, and more harm than good will result from such use. The reason is that a permanent falling of the hairs is required, temporary epilation with subsequent regrowth is not sufficient. Such permanent epilation can be secured, but it requires an erythema dose, one and one half skin units, and applied to the face of a woman, such doses will invariably produce a first degree radiodermatitis, followed after a time by pigmentation, telangiectasis and slight atrophy, a condition more unsightly than was the hypertrichosis. For this reason dermatologists advise against x ray treatment for this condition.

TUBERCULOSIS OF THE SKIN.

Another group is that of the infectious granulomata, in which the pathological process is infiltration with lymphocytes, giant cells, plasma cells and epithelioidal cells, besides new connective tissue spindle cells. This process is quite resistant to x rays and requires fairly large doses repeated many times. An example of this is lupus vulgaris, true tuberculosis of the skin. The Finsen light having proved an impracticable treatment in this country, x ray is the best treatment at our disposal, and will produce cures or marked improvement in over half of all cases of lupus vulgaris, whether favorable or not. The amount of ray used is one half or three quarters of the unit, depending on the clinical type and the age of the patient. This dose is repeated every two or three weeks. To obtain results, this should be persisted in for from six to twelve months. Lesions of any part of the body may be so treated, and tuberculous lesions of the mucous membrane of mouth, nose, and throat may be treated by filtering the rays, thus using only the most penetrating rays, and sending in a correspondingly larger amount through the skin surface above the mucosa lesion. Scrofuloderma, tuberculous adenitis, and tuberculosis orificialis yield in the same manner, and in these types of tuberculosis the prognosis for cure is good.

Other granulomatous diseases of the skin yielding to x rays are blastomycosis, sporotrichosis, and actinomycosis, mentioned before, erythema induratum, mycosis fungoides, leucemia of the skin and others.

BASAL CELL EPITHELIOMA.

Malignant disease of the skin is the last group to be considered, these diseases requiring the largest amounts of x rays given. The type of malignancy of the skin most often treated, and yielding best results, is basal cell epithelioma, or rodent ulcer, the type most commonly seen and relatively benign because it does not involve lymphatics and does not metastasize, though it spreads by extension both laterally and inwardly, and can destroy any tissue it infiltrates. There is no doubt that an adequate dose of x rays will kill epithelioma cells, and this can be done with an amount that will not seriously harm the skin. The records of x ray treatment show that ninety-five per cent. of permanent cures can be had in selected cases, and eighty-five per cent. of cures in unselected cases, the latter class including all cases applying for treatment, even though advanced, neglected or improperly treated.

Those results are as good, if not better, than the results of treatment by surgical excision or any other method in use, and because of such results, x ray treatment of basal cell epithelioma is well established as the method of choice. The special advantages are: First, the facility with which certain localities are reached by rays, such as inner canthus of eyes, nasolabial folds, etc., where excision is difficult. Second, the avoidance of disfigurement which follows excision on the face, and over half of all basal cell epitheliomata occur on the face. Third, with radiation it is simple to treat in addition to the growth, a wide enough margin of apparently normal skin to be sure of killing all lateral extensions of the process. This advantage is clear in treating epitheliomata on the eyelids, about the inner canthus of the eyes, and on the nose, where surgery may at times find it impossible to excise the necessary margin. Finally, there is avoidance of pain, shock, and the dread of operation, and a minimum of scarring and disfigurement.

The technic of treatment is to reach every cancer cell with a full lethal dose, no less. For cutaneous treatment this is from one and one half to two units of unfiltered rays, and this amount must reach the undermost and innermost layers of epithelioma cells, as well as those on the surface. This is the main point to be remembered. X rays are absorbed and their quantity diminished by every layer of cells they traverse, and if one in treating an epithelioma of any thickness calculates to supply two units of x rays at the surface, so much of the rays would be absorbed on passing through the layers of cells that the quantity reaching the lowest levels of the growth would be diminished to much less than the lethal dose, and any quantity less than a lethal dose is likely to stimulate the growth and division of cancer cells. The lowest and deepest layers of the epithelioma are the fastest growing, and the full dose must reach there. If the epithelioma is not thick, the unfiltered rays alone may be depended on. If the lesion is at all thick and bulky, then as much of the mass as is possible should be removed with a curette. This is done under local anesthesia, and does not aim at complete removal, but, by removing the great bulk of malignant tissue, brings to the surface and renders more accessible to the rays the deep layers and lateral extensions of the epithelioma. So the rays reach these layers, where cells are dividing fastest, in undiminished, effective amount.

With or without curettement, one and one half to two units of unfiltered ray is given to the known area of malignancy and to a margin of skin one half inch wide on all sides. After four to six weeks, the same dose is repeated, and again repeated after the same interval, until a clinical cure has been obtained.

If the physical character of the growth is such that the lowest layers cannot be exposed by curettement, and it is evident that unfiltered rays will not be sufficiently penetrating, then the rays are to be filtered through metal, usually three mm. of aluminum, to increase the proportion of deeply acting rays. Filtered radiation is indicated in deeply seated and greatly indurated lesions, and especially if muscle, bone or cartilage is involved. The formula given before for the unit of unfiltered x ray does not hold for filtered radiation.

The cause of failure in treating basal cell epithelioma is, in short, failure to destroy the lowest level of malignant cells. This may result from insufficient dosage, but most often from failure to curette or treat with filtered rays a thick deeply seated growth. Such cases will seem to be cured, but after some months will show relapse. An epithelioma which has been mistreated or inadequately treated by x rays may acquire an immunity against radiation that will make this agent powerless against it. Previous treatment by caustics, cautery or any agent that does not completely remove the malignancy but only irritates it, may make hopeless for radiation a case that should have been favorable.

OTHER TYPES OF SKIN MALIGNANCY.

Prickle cell or squamous cell epithelioma is much more malignant than the basal cell type, as it early involves the lymphatics and sends metastasis to nearby parts. However, this epithelioma always starts as a local growth and in this stage x rays are highly efficient, though the cells of prickle cell epithelioma are inherently more resistant than the cells of the other type. Large doses, two units, must be used, with filtration or curettement to meet the problem stated before. At the same time the lymphatic paths should be rayed even if no extension there can be demonstrated. When metastasis has occurred x ray alone should not be depended on, but surgical eradication of all areas should be done in conjunction with vigorous radiation.

The various types of sarcoma of the skin are rare, and not much experience has accumulated. They seem susceptible to x ray, and are treated like epithelioma of the squamous cell type. The socalled sarcoma of Kaposi is curable by x rays.

Of the preepitheliomatous lesions, the senile and seborrheic keratoses can be eradicated by erythema doses of unfiltered ray. Leucoplakia doses not respond.

MISCELLANEOUS DERMATOSES.

To complete this account of cutaneous therapy, mention should be made that excessive function of skin glands is controllable by x rays, and hyperidrosis and bromidrosis are so treated. The antipruritic effect of x rays leads to their use in treating pruritus ani and pruritus vulvæ. Most of those suffering from these distressing conditions can be quickly relieved of the itching, and some permanently cured. There are other indications for x ray therapy in dermatology, but those considered are the most important and illustrate the principles of treatment.

528 Delaware Avenue.

SEBORRHEAL DERMATITIS

By Samuel Feldman, M. D.,
New York,
Associate Dermatologist, Beth David Hospital; Adjunct Attending, Bronx and Lebanon Hospitals, Departments of Dermatology and Syphilis.

The beneficial effect of the rays from the quartz mercury lamp on seborrhal lesions is now generally admitted by dermatologists familiar with its action. As this action is due to actinic rays which occupy the same position in the solar spectrum as the ultraviolet rays of the sun, the beneficial action of sun light in this disease must be conceded. For the original should be at least as effective as its substitute. The same, however, can not be said about the influence of frequent washing and bathing in patients with seborrhea. It can not be said whether it helps its prevention, whether it increases the predisposition to the disease, or whether it influences an established case of seborrhea one way or the other.

The late Dr. Gottheil argued, and some of the men formerly associated with him still hold, that frequent washing of the head is beneficial in preventing this disease. To substantiate this claim, the South Sea Islander is brought forward as an example. These people spend most of their time diving in the ocean, and it is asserted that seborrheal alopecia is unknown among them. This argument would be sufficient, if it could be established that the only difference in the mode of living between the South Sea Islander and civilized mankind is his sea diving occupation and pastime. This, however, is not the case. There is no doubt in the mind of the author that clothing worn by the city dweller, especially the black felt hat which completely prevents the sun rays from reaching and exerting its beneficial influence upon the skin, indirectly predisposes to seborrhea and its accompanying alopecia. For the same reason, seborrhea is unknown among savages who have no use for hats and wear but little clothing on their bodies.

The following case, which I saw in consultation with Dr. J. Landy, on July 11, 1923, confirms me in this belief.

Case.—The patient, a young man, about twenty-eight years of age, stated that for several years he had had a moderate amount of dandruff. He had been spending the entire summer at the seashore and still resided there. His clothing for the greater part of the day consisted of a dark colored bathing suit. About ten days prior to the date on which I saw him, an extremely itching eruption had developed.

On examination the patient presented a unique and striking picture. The entire torso, front, back, and sides, also the uppermost portion of the thighs, were covered with brownish red patches of seborrheal dermatitis. Some of the patches were covered with muddy yellow and greasy scales. The eruption was strictly limited to the portion of the body covered with the bathing suit. It ended in a sharp margin exactly where the edge of the bathing suit came. The line of demarcation was still further enhanced by the deep tanning of the exposed portions of the body, where not the slightest evidence of any lesions could be found.

The conclusions drawn from this case are:

1. That the sun rays prevented the disease from appearing on the exposed portions of the body.
2. That the frequent salt water bathing had no beneficial effect, and possibly the opposite was true.
3. That the frequency of seborrheal alopecia in civilized men and its absence in the savage was due to the clothing the former wears.
4. That this disease was more common in men than in women because the former was more thoroughly covered.

1955 Grand Concourse.

AN UNUSUAL CASE OF PURPURA

By Louis H. Sigler, M. D.,
Brooklyn, N. Y.

Purpura may be conveniently divided into two groups, one in which it is a symptom accompanying many definite diseases, the other in which it occurs independent of any known disease. In the latter group we have the pure hemorrhagic form—where all the associated systoms are dependent upon bleeding or the loss of blood—and the socalled rheumatic form, in which, associated with the bleeding, there are some arthritic or rheumatic manifestations.

The substitution of the term rheumatic for the usual textbook term arthritic I think is justifiable. There are many cases on record which can not be fitted in or considered as simple purpura, Schonlein's disease or Henoch's purpura, for lack of definite joint symptoms, and yet can not be classed as hemorrhagic purpura for the presence of various muscular or other vague aches or pains, which for lack of better knowledge, are classed as rheumatic manifestations.

In this subgroup of purpura may perhaps be placed the following case which we recently observed in the Williamsburgh Hospital:

Case.—S. R., fifty years of age, Russian Hebrew, male, married, occupation baker, was admitted August 4, 1922, with complaints of severe swelling of right chest and left upper thigh. These swellings began to develop on August 3 and gradually grew larger. The condition apparently came on suddenly without any warning signs or premonitory symptoms. He stated, however, that about one month previous to onset he had severe neuralgic pains in the right arm and right side of chest which lasted about two days, but disappeared never to come back.

In his family history nothing abnormal was mentioned, while his past personal history was that of a fairly normal person. He never had any bleeding, nor were there any bleeders in his family. He never suffered from any of the infectious or contagious diseases. He had a productive cough and occasional night sweats within the past year, but there was no loss of weight, no weakness, hemoptysis, fever, dyspnea or palpitation. Appetite was always fair. He never suffered from nausea or vomiting, never had melena, hematemesis or jaundice. He never suffered from any genitourinary symptoms and denied luetic or Neisserian infections. Sexual functions were normal. He has eight children, all of whom are healthy, except one, who for the past eight months, has been suffering from an affection which according to his description would correspond to tuberculous pleurisy. I had no opportunity of seeing that case. He always lived under unhygienic conditions, during the day working in a dark cellar as baker and at night living in dingy, poorly ventilated rooms. His habits were always fairly normal, except that he indulged in excessive tobacco smoking, using twenty to thirty cigarettes a day. He never indulged in alcohol, and always lived on a well rationed diet.

The physical examination on day of admission showed a male of about forty-five years of age, emaciated, cachectic and moderately anaemic. Cheeks were drawn in and bony parts of face stood out prominently. He had anxious gaze and appeared to have little pain. Head did not show any marks of injury or abnormality. Eyes were normal, pupils of equal size, moderately contracted, and reacted to light and accommodation. Mouth had many false teeth and his own few teeth were poorly kept. Gums were not spongy and, except for a little pyorrhea, were of normal appearance.. Chest had marked massive swelling over the entire right axilla, right anterior and right posterior portions, covering an area extending from the apex of the axilla down to the seventh rib and from right sternocostal junction anteriorly to right spine posteriorly, and displacing the scapula upwards. Mass was tense, somewhat tender and fluctuating. The color was somewhat darker than the normal adjacent skin. An estimation of the approximate size of the right side of the chest as compared to the normal left side, was eight inches more. In other words, placing the normal circumference of his chest at thirty-two inches, in this case it was about forty inches, the right side being twenty-four inches and the left sixteen inches. An approximate amount of fluid this mass should have contained can be placed at one quart. The left chest was normal in appearance. No abnormal signs could be detected revealing any pathology within the chest. Abdominal findings were entirely negative. Spleen was not palpable. Extremities were normal in appearance except that over the left upper thigh, extending from Poupart's ligament down to about three inches above the kneejoint, in its inner part, there was a swelling similar in appearance to that of the chest, but of smaller size.

Outside of these two masses there was absolutely not a typical purpuric spot to be found, and applying the turniquet test we could not produce any such spots. X ray revealed no pathology other than the infiltration of overlying soft parts.

Throughout his stay in the hospital of two weeks, there was little change in sizes of both masses, but the consistency and color changed materially. The first seven days the consistency was fluid, as shown by fluctuation, and gradually became more solid. Aspiration on the first day yielded clear, uncoagulated arterial blood, while ten days later aspiration yielded nothing, and tumor felt solid. Color likewise underwent gradual change from slightly darkened hue on the first day to blue color three days later, yellowish blue at the end of ten days and brownish yellow on the day he left the hospital—all of which are typical blood changes in ecchymosis. Discoloration of chest extended down to the pelvis, covering right abdomen and flank.

His general condition was grave the first seven days. He seemed to have suffered greatly from the loss of blood. He was very weak, had headaches and occasional dyspnea. He coughed frequently, was restless and slept poorly. His temperature varied from 99 to 100 degrees, pulse 70 to 100 and respiration 20 to 30.

The urine was entirely negative on two different days. Blood count on the second day showed red blood cells 4,350,000, white blood cells 9,200, hemoglobin 85 per cent., differential count normal. On fourth day the white blood cell count was 13,000 with a differential of 76 per cent. polymorphonuclears, ten per cent. small mononuclears, twelve per cent. large mononuclears, and two per cent. eosinophiles. On the ninth day, the red cell count was 3,340,000, the white cell 10,500, with a differential of 70 per cent. polymorphonuclears, ten per cent. small mononuclears, twelve per cent. large mononuclears, and 3 per cent. eosinophiles. The blood platelet count on sixth day was 430,000 and coagulation time was four minutes. Feces was negative to parasites, mucus or blood. Tuberculous fixation test was positive and Wassermann test negative.

Twelve days after admission, the general condition markedly improved, and the patient, insisting upon going home, was discharged at end of two weeks. I saw him three days later and again about four weeks after his discharge. At that time, both masses had entirely disappeared under potassium iodide treatment. Generally, he was in much better condition which may be accounted for by the fact that he changed his occupation from baker to that of peddler on the street. He complained, however, of weakness and occasional pain in right arm. Physical examination then revealed some râles at both apices posteriorly with signs of partial consolidation in the same areas. There were also some râles heard at left lower base posteriorly.

The outstanding features in this case were:

Localization of subcutaneous hemorrhage to only two superficial parts of body, involving fairly large blood vessels. Absolutely no bleeding from any of the mucous surfaces. No typical intracutaneous hemorrhage, exhibiting itself in form of purpuric spots, and none could be produced mechanically. No history of hemophilia. Normal blood platelet count, but some increase in white cell count with relative increase in large mononuclears, some of which might have actually been bone marrow cells. Delayed coagulation and deficient contractility of blood clot within the body for several days, while the laboratory coagulation time was approximately normal. Complete absorption of both masses and recovery of patient with no sequelæ (except slight pain and weakness of right arm) and no recurrence of condition at present writing. Evidence of inactive pulmonary tuberculosis.

With these findings before us, the questions arise: Are we dealing with a case of purpura? If so, what form is it and what is its etiology?

That it is a case of purpura is evidenced by: 1, long delayed coagulation time and deficient contractility of blood clot, while laboratory coagulation time was normal; 2, by relative increase in large mononuclears, some of which might have been bone marrow cells; 3, by exclusion of all other possible conditions that might give rise to such bleeding. Thus, trauma is excluded by history; malignancy is excluded by negative x ray findings and by condition clearing up; pulmonary tuberculosis with intrathoracic erosion of a blood vessel and hemorrhage finding its way outwards, is excluded by the presence of a similar bleeding in the lower extremity; ruptured varicose veins is excluded by location, lack of varicosities and by blood being arterial; ruptured aneurism is excluded by negative Wassermann, negative physical findings and by complete disappearance of ecchymosis.

As to what form of purpura this is, it is hard to tell. It can not, strictly speaking, be considered as hemorrhagic purpura, not having been accompanied by hemorrhage from any of the mucous membranes, and having run such a mild course with complete recovery. It can not be placed among Henoch's purpura and Schonlein's disease. A good name would be simple hematomatous purpura—simple, for its uncomplicated course and hematomatous, to designate the extent of bleeding.

The etiology of this form of purpura, like that of any other form, is obscure. To say that poor hygienic surroundings, excessive smoking, debility and possibly latent tuberculosis that we found in this case, are the causes of this disease is not correct. Most persons that we find under the same conditions do not show this disease. We can also rule out heredity, unbalanced and poor diet, and idiosyncrasy. We thus come down to some unknown infection or toxin, or most probably, mixed infections or toxins as being the possible causes of this and all other forms of purpura. The infections or toxins attack either the blood forming organs, modifying the composition of the blood, or the vasomotor system or the blood vessel wall itself. In some forms all parts are equally attacked, in others, some are spared.

Dermatological Therapy.—Veyrières (*Bulletin médical,* October 6, 1923) asserts that poor results from external remedies in skin diseases are often due to improper formulation of the preparations prescribed, and criticizes various formulæ in use at the Saint Louis Hospital, Paris.

Petrolatum, while it does not become rancid, is disadvantageous in that its solvent powers are practically limited to iodine and the phenols; it does not penetrate the epidermis, and therefore does not assist the penetration of substances incorporated in it; above all, its melting point is too low, so that ointments made with it fuse, and spread over the skin surface or are absorbed by dressings, thus removing the incorporated drugs from contact with the skin. This defect can be obviated by incorporating in the petrolatum a considerable amount of paraffin.

Cerates and cold cream form better excipients and penetrate the cells of the horny layer. Even these products are somewhat too soft, especially in the summer; this is corrected by increasing the customary amount of wax, or better, by adding one fifteenth or one tenth part of wool fat. To prevent rancidity of cold cream or cerate, all or part of the aromatic waters used in their preparation may be replaced by lime water, the calcium of which saturates the fatty acids in the preparation as fast as they are formed. Lime water can be incorporated in lard by first absorbing the former with lanolin and then mixing the latter with the lard. Bismuth and zinc oxide in sufficient amounts will also saturate the fatty acids.

A three per cent. ointment of salicylic acid in petrolatum is not at all likely to be active because salicylic acid is not dissolved in the excipient. The acid will dissolve in oil, which can then be thickened with wax or stearin, but this will never yield a preparation stronger than three per cent. For a stronger preparation it is best to make a twenty per cent. solution of salicylic acid in water to which boric acid has been added, absorb this solution with lanolin, and incorporate the latter with the main ointment base. One part of iodine in fifty parts of petrolatum makes a very satisfactory ointment; a three per cent. ointment is also feasible.

For a sulphur lotion, the author endorses Huerre's formula: precipitated sulphur, 7.5 parts; powdered soap, three; glycerin, eight; alcohol, eight, and distilled water, fifty. In prescribing oil of cade, glycerin preparations should be replaced by cerates, that is, oil of cade thickened by addition of yellow wax. A strong preparation can be made with only one third or one fourth of the formula consisting of wax; if desired, the oil of cade can be diluted with some vegetable oil.

If a preparation which can be more easily removed from the skin with water is desired, some lanolin can be added to the cerate; for a relatively weak action, one part of oil of cade to two parts of lanolin may be used. An excellent preparation, easily removed with water, and containing a maximum of forty per cent. of oil of cade, is made by saponifying the oil with one centigram of saponin per gram of oil, and the yolk of one egg, this being then incorporated in lanolin.

Abstracts from Current Literature

DERMATOLOGY.

A Suggested Etiology of Bakers' Dermatitis.—Oscar de Jong (*Lancet,* May 5, 1923) believes that salt may be justifiably regarded as the direct cause of the condition, but the patient must display an idiosyncrasy for the salt, as the condition is not found in all bakers. It is interesting to note that dermatitis also occurs in other people who are habitually engaged in the handling of salt, such as herring salters, packers, and rock salt workers. The important fact remains that a person can be cured under very simple treatment on being removed from his work if there are no secondary symptoms, but that a relapse will occur when he returns to work. A prophylactic measure is the provision of running fresh water under which the man might rinse his arms from time to time.

Influence of Intravenous Injections of Mercury Benzoate on Wassermann Reaction.—Strickler (*Journal of Laboratory and Clinical Medicine,* April, 1923) selected twelve patients suffering from various skin conditions, especially the chronic dermatoses, giving them mercury benzoate intravenously at weekly intervals, varying the dose from two fifths to three fifths of a grain. Eleven patients had a negative Wassermann before these treatments, and one a four plus at the beginning, which was unaltered after twenty mercurial injections. In nine of the patients the Wassermann reaction remained negative. In one instance it became doubtful after the twenty-second injection, and negative after the twenty-ninth. Another patient with an acute psoriasis of nine months' duration in whom the Wassermann was negative before treatment developed a four plus reaction after the twelfth injection, which persisted after the eighteenth, when the patient disappeared. The author does not believe that the Wassermann reaction is influenced by the intravenous use of the mercurials.

Socalled Dermatitis Exfoliativa.—After studying an epidemic in a children's hospital, E. Wieland (*Schweizerische medizinische Wochenschrift,* December 21, 1922) came to the conclusion that there is only a gradual difference between pemphigus contagiosus and dermatitis exfoliativa. In every one of the author's twelve cases, the Staphylococcus pyogenes aureus was present. The infection originated in a girl who was affected with a panaritium and who laundered the diapers.

The treatment is strictly antiseptic. Isolation of the patient is always indicated, inasmuch as the contagion spreads by contact infection. The prophylaxis requires the most careful asepsis. The individual vesicles and blebs must be opened aseptically at once and the blebs must be thoroughly dried by complete removal of the covering skin and by the absorption of the infectious content by sterile cotton sponges in such a manner as to avoid contamination of the surrounding skin (autoinoculation). The moist, red base of the vesicle should be moistened either with alcohol or a three per cent. solution of silver nitrate, or touched lightly with a stick of silver nitrate. An antiseptic powder (dermatol) is then applied as thickly as possible. This treatment is repeated as soon as a fresh vesicle appears, at least two to three times a day. An antiseptic bath may precede the opening of the vesicles. The healthy skin should be kept dry with powder. Small pustules or folliculitides should be ruptured with alcohol sponges and treated with tincture of iodine or incised. Those portions of the skin which have folds, or are exposed to trauma, and those around the mouth and nose require particular attention. In severe forms the bath and salve treatments are contraindicated; the child should be kept naked and merely wrapped in sterile gauze.

Röntgen Ray Treatment of Skin Diseases.—Clyde K. Hasley (*Medical Clinics of North America,* March, 1923) says that the rays of a long wave length are especially indicated in the treatment of superficial dermatoses. The therapeutic effect is apparently due to the absorption of rays by the tissues through which they pass. The various wave lengths differ in their ability to penetrate tissues of the body. For superficial skin lesions the question of penetration is not as important as the question of dose, but for deep therapy improper penetration, with imperfect depth dosage in consequence, results in disappointing failures. The method employed was, in the main, that taught by Zwawulenberg, excepting the use of a longer spark gap, higher milliamperage and usually a filter. Mycelial dermatitis, senile keratoses, and other squamous eruptions yield more promptly to the unfiltered than to the filtered rays. The aluminum screen enables us to give longer exposures and diminishes the chance of producing a burn by filtering out the soft rays which act so readily on the skin. In the hands of a novice filtered rays are much safer than the unfiltered. Röntgen rays, properly applied, are the most useful single therapeutic agent in the hands of the dermatologist.

Hypersusceptibility in Constitutional Eczema of Infants.—E. Gartje (*Monatsschrift für Kinderheilkunde,* April, 1923) asserts that there is a group of children who are affected with constitutional eczema and who show a hypersusceptibility of the skin toward fats, which is expressed in the eczema. These children are characterized by thinness, a dry eczema, and are usually free from other exudative phenomena. Fatty food or the administration of fat aggravates the eczema, and the exclusion of fat causes it to recede or to disappear entirely. Codliver oil acts in the same manner in this respect. The author believes in the theory that milk fat is the etiological factor responsible in these cases and would therefore exclude all fat from the diet, with the reservation that this applies only to the group of constitutional eczema. Inasmuch as injections of butter and oil seem to lessen the hypersusceptibility of the skin, a certain therapeutic significance may be attached to the intracutaneous injections of solutions of fat in obstinate cases.

SURGERY.

Curettage of the Conjunctiva in Chronic Catarrhal Conjunctivitis.—Nikolaus Blatt (*Wiener klinische Wochenschrift,* December 28, 1922) states that the curettage of the conjunctiva is indicated in all cases of chronic catarrhal conjunctivitis which persist in being refractory toward all the other methods of treatment. The technic is the same as in trachoma: with the aid of a scalpel or a small curette, constructed along lines similar to the instrument used for gynecological purposes, the epithelium is energetically scraped off everywhere. In this procedure, the lids must be pressed against a hard object in order to reach the subepithelial tissue superficially.

Prognosis of Luxations of the Shoulder.—Hans Gubler (*Schweizerische medizinische Wochenschrift,* September 28 and October 5, 1922) comes to the conclusion that the prognosis of simple uncomplicated luxation of the shoulder is good and that the period of cure is an average of thirty-eight days. The prognosis is dependent upon the age of the patient: the older the patient the longer does it take to heal and the greater the percentage of invalidism. The prognosis of right sided cases of shoulder luxation he found somewhat poorer than that of the left sided cases. Unskilled laborers required a longer period of healing than able and intellectual mechanics. The prognosis of uncomplicated shoulder luxation may be improved from the beginning if motion therapy is begun from the very first day after the reduction. The prognosis of complicated shoulder luxations is, a priori, poorer. It depends, most of all, upon the nature of the complication. The worst prognois is observed in luxations with paralyses of nerves, both as to the period of cure and as to invalidism. The cases complicated by fracture of the greater tuberosity show an average period of healing of eighty-two days and an invalidism of seventeen per cent. Of all complicated luxations, only seventy per cent. heal without a permanent injury. The prognosis of habitual luxations is poor because of the danger of recurrences; no method of treatment that promises success has as yet been found.

Indications for Schede's Operation in Empyema.—Makato Saito (*Mitteilungen aus der medizinischen Fakultät zu Tokyo*) does a resection of the eighth or ninth rib and inserts a rubber tube into the thoracic cavity and irrigates it. By irrigating and measuring the capacity of the empyemic cavity with warm water, the changes in the capacity of this cavity are determined. These changes in the capacity are represented graphically by making the time the abscissa and the capacity of the cavity the ordinate. The point of crossing of these two factors forms a curve, which is called the curve of capacity of the empyemic cavity. This curve is useful, 1, in determining the healing of the empyema; 2, in determining the indication for Schede's operation; and 3, in judging the result of the various forms of treatment. Röntgenography is essential in placing of the indication for Schede's operation. In the treatment of empyema after the thoracotomy, the treatment with Perthes's apparatus is absolutely necessary in order to avoid a chronic empyema.

Use of Large Reverdin Grafts in the Healing of Chronic Osteomyelitis.—Mont R. Reid (*Bulletin of the Johns Hopkins Hospital,* November, 1922) describes a method for treating certain bone cavities remaining after operation for chronic osteomyelitis. It consists essentially of epithelializing the walls of bone cavities by the use of large Reverdin or pinch grafts. The technic of skin grafting is as follows: The bone cavity is treated with Dakin's solution until it becomes lined with clean firm granulations. Without the use of Dakin's or some other antiseptic solution the granulation tissue becomes edematous or "seaweedy," and forms an unhealthy base for the growth of grafts. Two hours after the last irrigation with Dakin's solution large thick pinch grafts, half a centimetre in diameter, are placed closely together upon the surface of the cavity. The grafted wound is then exposed to the air for from six to eight hours. This short drying period serves to fix the grafts firmly to the granulation tissue. The grafts are then covered and held in place with a single layer of gauze which is firmly secured to the normal skin so that the moistening and changing of saline compresses during the next two days will not displace the grafts. After two days the grafts have taken and the use of Dakin's solution instead of salt solution is begun. This is applied by laying wet compresses directly against the wound (the thin layer of protecting gauze having been removed) every two hours during the day and every four hours at night. After about five days the Dakin's solution is discontinued and the wound is dressed with rubber "protective" or old linen. Invariably the grafts grow quickly and cover the granulation tissue with epithelium in from ten days to two weeks. Should the granulations become high (usually from the edema of infection) caustics should not be used; Dakin's solution reapplied for one or two days will reduce the swollen granulations to the level of the grafts, and will not injure the growth of new skin. With such a method of treating chronic osteomyelitic bone cavities the time required for curing the most stubborn cases is usually from four to six weeks.

Closure of Granulating Wounds with Reverdin-Halsted Grafts.—Karl Schlaepfer (*Bulletin of the Johns Hopkins Hospital,* April, 1923) describes the technic of the Reverdin-Halsted grafts which is the method of choice at the Johns Hopkins Hospital in treating defects following extensive laceration of the soft parts with secondary necrosis and suppuration, the grooves resulting from sequestrotomy for chronic osteomyelitis, and some cases with granulating areas following unsuccessful plastic operations for empyema. The method has also proved useful in the treatment of x ray burns and of trophic nonspecific ulcers of long standing which have been refractory to all other measures. In every case a smear must be made from the wound to determine its bacteriological condition. Dakin's solution is used in the preliminary treatment until relative sterility is obtained, when the grafting with small deep grafts is done. Schlaepfer states that every infected wound not suitable for secondary closure can be successfully covered with a very resistant, elastic skin by means of the Reverdin-Halsted transplantation.

Experimental Surgery of the Thoracic Esophagus.—Robert T. Miller, Jr., and W. D. W. Andrus (*Bulletin of the Johns Hopkins Hospital,* April, 1923) report work on dogs which demonstrates that a suture of the esophagus can be made so as to hold securely and to result in satisfactory healing, an intact functioning anastomosis being obtained in eleven animals. It also demonstrates a fairly satisfactory substitute for at least the lower two thirds of the tube, and the presence of a well developed submucosa in the human esophagus. The surgical method is described in detail. The futility of the present management of cancer of the thoracic esophagus would seem sufficient justification for undertaking promising procedures, even though they involved a greater risk than one would willingly assume.

Tuberculosis of the Sacroiliac Joint.—H. C. Wardleworth Nuttall (*Lancet,* April 28, 1923) believes that the old operations of trephining and scraping are not based on sound conceptions of the anatomy and pathology of the joint; also that the results of these operations are poor according to his experience. Much better results are to be expected from the more radical treatment, such as Picque's method, which is as follows: 1, approaching the joint by cutting away the posterior overlapping portion of the ilium; 2, the resection of more or less of the sacrum, as may be necessary, for the complete evacuation of any intrapelvic abscess; 3, the methodical following up of the disease by means of the gouge or curette, so that a smooth granulating surface may be formed without pockets or sinuses.

Treatment of Clavicle Fractured by Indirect Violence.—Frank Romer (*Lancet,* May 5, 1923) asserts that treatment depends upon the control of the outer fragment by means of the intermediary, the scapula. In order to reduce the deformity he raises the arm on the injured side to a right angle with the body, thereby bringing the outer fragment up to the level of the inner fragment. The patient's both shoulders are then firmly drawn back, so that the scapula is pushed back as far as possible, the arm being kept raised at a right angle. Having effected reduction of the deformity in this manner, apposition of the fragments is secured by fixing of the scapula in the position in which it now lies by placing a thin layer of gamgee tissue or cotton wool in the axilla, fixing a long strip of adhesive plaster to the top of the shoulder joint just over the acromion and bringing it up under the axilla to the front where it crosses over the top of the shoulder at the acromial end of the clavicle. This strip, which encircles the shoulder joint, is brought diagonally across the scapula to below its angle. A second strip of plaster, about one and a half inches wide, is attached just above the nipple and brought with firm pressure over the clavicle to below the angle of the scapula. A third and a fourth piece are then applied in the same way, slightly overlapping each other, and covering the entire surface of the clavicle. The arm is then gently lowered and the patient is allowed to dress himself in the ordinary way. The only support necessary is an ordinary sling, which is worn for the first two days. The use of the arm should be restricted to underhand movements. Skilled massage is applied daily for at least a week. After ten days the sling is discarded and the arm be put to general use. The strapping should be renewed after four days and again as may be necessary for at least three weeks.

Open Ether for the Occasional Anesthetist.—Among the advantages of the open ether method of administration, over the old ether cone method mentioned by Arthur Waters (*Lancet,* April 28, 1923) are: 1, an efficient apparatus can be made in half an hour; 2, the mask being warm and damp at the start, the inhaled vapor tends to irritate the mucous membranes to a minimum degree; 3, the patient's forehead and eyes are uncovered and easy of inspection; 4, going under is infinitely less disagreeable to the patient than the method so often adopted in which the whole face is covered with cotton wool and a low mask upon which ether is slopped promiscuously. The felt masks are best cleansed by careful washing, followed by a soak in 1:40 carbolic solution. Too much boiling causes them to shrink very rapidly and to become hard. The shrunken masks may be used for children.

Treatment of the Internal Derangements of the Knee Joint. A New Method of Operative Exposure.—A. G. Timbrell Fisher (*Lancet,* May 12, 1923) secures adequate exposure of the knee joint by making a slightly curved incision, commencing above in the median line, an inch above the uppermost limits of the suprapatellar pouch, skirts the inner border of the ligamentum patellæ and of the patella and ending below slightly to the inner side of the tubercle of the tibia. The flap of skin and subcutaneous tissues is reflected outward to slightly beyond the outer border of the patella. The patella is dislocated to the outer side of the joint, and on further flexion of the joint an excellent exposure of the whole of the anterior compartment is obtained. This procedure obviates the introduction of the finger into the joint as every part of the joint is exposed to view.

Treatment of Acute Suppurative Infections of the Hand.—John R. Griffith (*Clinical Journal,* September 5, 1923) deals with infections of the finger pulp, the nail bed, the midpalmar space, the thenar space, the fascial space in the forearm, and the tendon sheaths.

There are a few important points in the technic of these operations. The field must be bloodless, in order to enable one to see where the pus is coming from and to follow it up. A tourniquet is, therefore, always used, and the best form of tourniquet is a blood pressure apparatus round the upper arm; it can be easily controlled by the anesthetist. It is essential to avoid injuring nerves, therefore the method of opening up the deeper tissues described by Hilton is invariably used. Drainage tubes should never be used; gauze ribbon soaked in liquid paraffin is sometimes used for draining tissue spaces. No foreign body should ever be left in a tendon sheath; it enormously increases the risk of necrosis of the tendons.

With regard to aftertreatment, early mobilization is of the utmost importance. Within twelve hours of the operation the patient is given a warm two per cent. saline bath and encouraged to move his fingers in it. Bleeding, of course, does take place, but not to a serious extent, and it has the advantage of relieving congestion. The baths are repeated twice a day until the suppuration shows signs of cleaning up. After each bath the patient washes his hands with soap and water; this relieves to some extent the extraordinarily uncomfortable feeling that follows a prolonged bath, and it also necessitates some degree of mobilization. If the incision is adequate, mobilization does not spread the infection. Later, when the discharge becomes serous, mobilization under radiant heat is of great value.

PEDIATRICS.

Occurrence of d'Herelle's Bacteriophages in the Stools of Infants.—Ludwig Surányi and Eugen Kramár (*Monatsschrift für Kinderheilkunde,* July, 1923) found that of the fifty filtrates of stools of infants tested, twenty-three showed a pronounced lytic effect (forty-six per cent.) The highly valent lysins originate, generally, from infants in the second half of the first year of life. The condition of the intestinal tract appears to be of some significance: of the twenty-three strains of bacteriophages, nineteen were derived from infants with healthy intestines and therefore normal stools contain the lytic agent decidedly more often than dyspeptic infants. The constitution seems to have an effect in so far as bacteriophages are found in infants with the exudative diathesis much more rarely than in healthy infants (14.2 per cent. in exudative diathesis, 56.7 per cent. in healthy infants). The occurrence of the bacteriophages does not depend upon the nature of the food. All the stool filtrates were tested against fifty-two strains of eight varieties of bacteria. There seems to be a certain regularity in the manner in which the various highly valent bacteriophages behave toward the diverse strains of bacteria. In the first place, the toxic strains of dysentery were attacked by the highly valent bacteriophages. In a more extended field of action, in the second place, are the strains of the atoxic dysentery group, then come the colon bacilli, and the members of the typhoid group come up for consideration only exceptionally.

Treatment of Infantile Scurvy.—The chief sources of the antiscorbutic factor or vitamine C are green, leafy vegetables, roots, tubers and fruits, although they vary greatly in richness of content while animal products contain relatively little. J. C. Gittings (*Archives of Pediatrics,* August, 1923) recommends in the treatment of frank scurvy in an infant, the free use of orange juice, from two to four ounces a day, diluted with water and in divided doses, as practically a specific. In the majority of cases improvement can be expected within forty-eight hours and a complete cure in two to three weeks. The results obtained with the juice of oranges obtained late in the summer are not always so prompt as with that of the oranges of the new fall crop. Failures in response may be attributed to severe gastroenteritis or secondary infections. If orange juice causes vomiting or fermentation, it may be added to double its amount of boiling water, cooled immediately and alkalinized by a pinch of bicarbonate of soda just before giving. Next in value to orange juice for infants is the strained juice of canned tomatoes, from four to eight ounces a day in divided doses. Even without other dietary changes, such measures are usually curative, but it is well to substitute raw milk for cooked milk in the formula, if the state of the digestion permits. Strained vegetable soup containing potatoes, onions and spinach may also be given. In the rare event of failure, in spite of these changes, freshly alkalinized diluted lemon juice in divided doses, two to three ounces a day, may be given. During the acute stage, when tenderness is marked, the handling of the child should be reduced to a minimum. In very severe cases, wet applications of a solution of magnesium sulphate applied over the swellings are soothing. The milk formula should be weakened and skimmed milk used in place of whole milk, where there is much indigestion or vomiting.

For the prevention of scurvy, human milk is almost a specific. Whenever it becomes necessary to feed milk which has been boiled or pasteurized, some form of antiscorbutic food must be employed, such as strained orange juice or strained canned tomato juice. A baby of four or five weeks can be given half a teaspoonful of orange juice twice a day diluted with water and slightly sweetened if necessary. This amount can be increased to a dessertspoonful twice a day, by the tenth to the twelfth week. The latter amount is sufficient as a routine antiscorbutic. If it disagrees, it may be scalded and alkalinized, as described. Tomato juice may be used in double the quantity of the orange juice. Another cheap substitute for orange juice is swede juice, obtained by scraping and pressing the raw vegetable. When strained, it can be fed in the same amounts as tomato juice. By the sixth month strained vegetable soup may be added to the diet, and with such safeguards, all danger of scurvy is obviated.

Secondary Anemia in Infancy.—Helen M. M. Mackey (*Lancet,* July 28, 1923) states that there is a general consensus of opinion that too prolonged and too exclusive a milk dietary produces anemia in infants and young children. This is probably due in part at least to iron starvation, on account of the low iron content of milk. Some writers, however, have held that it is directly connected with a toxic effect resulting from excessive milk consumption. Premature infants are known to be particularly prone to this form of anemia. In a group of thirty-six artificially fed infants, receiving milk or milk and carbohydrate diets, with or without codliver oil, anemia developed in the majority. It was usually noted toward the end of the first year of life, but sometimes appeared as early as the seventh month. Addition of vegetables to the diet at six or seven months did not prevent anemia. The infants were in well lighted and well ventilated wards, and were much out of doors in summer but very little in winter. Treatment by the administration of inorganic iron salts by mouth brought about improvement in the majority of cases treated, but not in all, possibly because the treatment was not continued for a sufficient length of time. No improvement was noted in the hemoglobin content of the blood in any case within three or four weeks from the beginning of treatment, and improvement might be delayed for six weeks with, thereafter, rapid proggress. It is suggested that many cases of anemia in infants, particularly in those artificially fed from an early age, are probably associated with iron starvation, more especially as it has been experimentally demonstrated that the iron rentention of an infant on cow's or goat's milk is much lower than on human milk.

Treatment of Active Infantile Tetany With Radiations from the Mercury Vapor Quartz Lamp.—Horton Casparis and Benjamin Kramer (*Bulletin of the Johns Hopkins Hospital,* July, 1923) exposed five children suffering from active tetany to the rays of the mercury vapor quartz lamp. Following raying, the clinical manifestations of tetany disappeared in from three to seven days, and the calcium concentration of the serum increased approximately to the normal. The inorganic phosphorus concentration of the serum was also raised to the normal level or above. The treatment, therefore, not only causes the subsidence of the manifestations of active tetany, but also cures the accompanying rickets. The effects of the rays were just as striking with negro children as with white.

Study of Hydrocele in the Nursling.—R. Vaglio (*Pediatria,* September 15, 1923) finds that a remarkable number of cases show the coexistence of congenital syphilis. Contrary to the view of Marfan he does not believe that unilateral hydrocele is always the type present in the luetic cases. The existence of a unilateral or bilateral nonreducible hydrocele should prompt a careful research as to the presence of lues. The rare cases of communicating hydrocele seem to have no connection with hereditary lues; tuberculosis seems to play no part in the etiology of hydrocele in the infant.

Intermittent Duodenal Obstruction in Children.—H. Olding Foucar (*Medical Clinics of North America,* July, 1923) reports two unusual cases of intermittent duodenal obstruction in children. In one, the obstruction was actually demonstrated to be due to an old adhesive fetal peritonitis, resulting in recurrent volvulus of the small intestines with closure of the duodenum. In the other, the obstruction was not demonstrated, but it was assumed from the case history that it was in the duodenum, and seemed to be due to the thickened edematous mesentery preventing free movement of the intestines within the abdominal cavity.

Empyema in the First Two Years of Life.—Hector Charles Cameron and A. A. Osman (*Lancet,* June 2, 1923) arrive at the following conclusions: 1. The high mortality of empyema in the first two years of life is due to the specific character of acute primary pneumonia of infancy. 2. In metapneumonic cases the patients almost always recover; in synpneumonic cases, they almost always die. 3. All metapneumonic cases should be dealt with by excision of rib as speedily as possible. 4. Synpneumonic cases should not be dealt with by excision of rib until after the termination of the pneumonic process; some form of paracentesis should be practised as a temporary measure. 5. In synpneumonic cases death occurs from the original pneumonia and from metastasis of infection to other parts, rather than from the empyema.

Pathogenensis of Rickets.—Eric Pritchard (*British Medical Journal,* May 26, 1923) asserts that the essential basis, or the *causa vera,* of rickets is most probably a relative excess of acid bodies produced in the system by a disproportion between the intake and the output of energy—a condition which results either from an innate inefficiency of the body machine itself, or from defects in the environment, the latter being regarded as including the quantity and the quality of the food, and the stimuli afforded by hygienic surroundings.

Action of Atropine and Pilocarpine on the Motility of the Stomach of Children.—M. Löwy and O. Tezner (*Monatsschrift für Kinderheilkunde,* July, 1923) found that if given in sufficiently high doses (up to two mg.), the subcutaneous administration of atropine leads to a retardation of the emptying of the stomach in children six to fourteen years of age. This retardation is probably due mostly to the diminution of the peristalsis and the tonus; furthermore, the permanent bulb occurs frequently. The general symptoms are slight and do not run parallel with the effect on the stomach. Pilocarpine, likewise, leads to a retardation of the time of emptying in fifty per cent. of the cases, probably as a result of the occurrence of spasms in the region of the pylorus and incoordinated peristaltic movements. The general effect is quite marked and shows a certain relationship to the condition of the stomach at rest. The differentiation of vagotonic types is impossible and age has no effect upon the action of atropine and pilocarpine upon the stomach.

Stridor and Dyspnea in Childhood.—Jesse B. Naftzger (*Journal of the Iowa State Medical Society,* September, 1923) classifies the causes as: 1, nervous disorders; 2, causes extrinsic to the larynx and trachea; 3, intrinsic causes. Nervous disorders comprise laryngismus stridulus and spasmodic croup, tetany and bilateral laryngeal paralysis. Extrinsic causes are enlarged mediastinal or cervical glands, enlarged thymus, retropharyngeal abscess, injuries, and foreign bodies in the hypopharynx and esophagus. Intrinsic causes are congenital stridor, new growths, stenosis from scars and burns, foreign bodies, acute inflammation and infections with or without membranous formation.

Cutaneous Tuberculin Test in Advanced Tuberculosis in Childhood.—Charles McNeil (*British Medical Journal,* April 21, 1923) makes certain modifications in the technic and reading of the Pirquet test, by means of which a positive reaction is obtained in the severe forms of tuberculosis, in which the diagnosis is verified by the finding of the tubercle bacillus and necropsy. A small area of the skin on the flexor surface of the forearm is chafed with the sharp point of a darning needle until the epidermis is removed and the pink cutis vera is exposed. Bleeding should be avoided. The eye of the needle is then charged with undiluted old tuberculin, and pressed into the prepared vascular surface with a rotary motion. This procedure differs from that advised by Pirquet in the careful preliminary excoriation of the skin, and thus renders more certain the contact of tuberculin with the skin capillaries. This difference is enough to secure success when the tuberculin reaction is feeble.

MALIGNANT GROWTHS.

Results of Radium Therapy of Carcinoma of the Uterine Cervix.—On the basis of sixty-three cases observed over a period of eight years, O. Beuttner (*Schweizerische medizinische Wochenschrift*, February 1, 1923) believes that the result of radium therapy depends not so much upon the microscopical appearance of the carcinoma or the number of millicurie hours applied, as on the age and general condition of the patient. The best results were observed in the older patients. Radioactive bodies are also given intravenously. The author's statistics show the great advantage of radium therapy, especially in the inoperable cases. In the nine operable cases, only four patients were cured by irradiation and in the right borderline cases, four patients were also cured. The author's experiments show that even if it is still a moot question whether operable carcinoma should be removed surgically or by irradiation, the latter gives better results in inoperable cases than the older palliative methods.

Rapidity of Growth of Carcinoma of the Uterus.—Walter Forst (*Zentralblatt für Gynäkologie*, May 13, 1922) states that the early subjective symptoms of uterine carcinoma are obstinate discharge, especially when it resembles the color of meat water, and hemorrhages after the onset of the menopause, as well as after douching and after coitus. The last is reported very often in cervical carcinoma. These symptoms are frequently present when macroscopically there is no irrefutable evidence of carcinoma and the diagnosis can then be made only after a microscopic examination of tissue. On the other hand, there are cases in which the cervix and even the vagina show, macroscopically, unmistakable carcinomatous tissue, without the patient mentioning any of these symptoms. Bleeding depends upon the structure of the carcinomatous tissue and no symptom is capable of indicating the age of a carcinomatous process. The other two symptoms, when caused by carcinoma, indicate degeneration of the carcinomatous tissue. Besides, the intelligence and cleanliness of the patient play an important part. A certain judgment of the rapidity of the cancerous growth can be made only when the whole process can be watched by the observer.

Such a case is reported in a woman, forty-nine years old, who complained of having bled for five months with freedom from bleeding at short intervals, after a menopause of two months' duration. A curettage stopped it temporarily. The general physical examination was negative. The vaginal portion of the cervix was somewhat hypertrophied and hard, and there was an extensive deep red erosion around the os, which bled at the slightest touch. The uterus was not enlarged and the adnexæ were free. An exploratory curettage and a biopsy on the vaginal portion of the cervix showed no histological evidence of carcinoma. The woman was examined vaginally regularly every two weeks and six days after a previously negative finding the hemorrhage reappeared together with a foul smelling discharge. About three weeks later, the patient appeared wretched and tired, and a vaginal examination revealed a cloudy, watery, stinking discharge, and the vaginal portion of the cervix was found transformed into a nodular tumor almost as large as a fist, from which large pieces of tissue could be easily broken off; on the left side, the tumor invaded the vagina and the left parametrium was rigid. The microscopical examination revealed a decomposing, pavement cell carcinoma. This condition was seen to develop within thirty-one days, indicating a very malignant course, which ended fatally.

Cancer in Cervical Stump.—Robert T. Frank (*Surgery, Gynecology and Obstetrics*, September, 1922), reports a case of stump cancer, noticed within five months after supravaginal hysterectomy for fibroids of the uterus. It is, therefore, fair to presume that the carcinoma was overlooked at the time of the operation. Complete hysterectomy for fibroids of the uterus is not recommended as a routine measure, because of its increased mortality over supravaginal amputation. Increased care in examining the cervix, before all operations for uterine conditions are undertaken, is enjoined and it is suggested that the patients after operation be warned to note and report bleeding or abnormal discharge. A metastasis in the nonadherent appendix is reported as a unique site of secondary deposit from cervical cancer.

Syncytioma of Uterus.—Henry E. Meleney (*Surgery, Gynecology and Obstetrics*, August, 1922) reports a case of atypical chorioma, in which the necropsy showed a small tumor in the right cornu of the uterine cavity, acute infection of the endometrium extending through vessels about the right fallopian tube, acute diffuse peritonitis, and hemolytic streptococcus bacteriemia. The tumor consisted only of syncytial cells lying singly and in clumps in the swollen stroma of the uterine mucosa and in the superficial portion of the myometrium. The case illustrates the importance of early determination of the cause of uterine bleeding, not only in order to deal properly with the tumor itself, but also to avoid a termination by acute general infection.

The Physician and His Relation to the Compensation Law*

By H. B. PRITCHARD, M.D.,
Syracuse, N. Y.

The compensation law covers a field that is so broad and ramifies in so many directions, that I feel it only fitting to treat the particular phase in which we are interested—the medical aspect.

Compensation legislation was in force in Europe for a great many years before the United States became interested in it. The first interest shown in this country was by its adoption for government employees, such as postal clerks, and it was not until 1910 that any state enacted such legislation. This was the state of New York, and was our first Workmen's Compensation Law. The Court of Appeals declared it unconstitutional in the Ives case and made necessary a constitutional amendment to the laws of the state. The delay occasioned by this, brought us into the year 1914 before we had our second law, which is the one under which we are now operating. In the meantime, several states adopted a compensation law, and since, most of the balance, so that at the present time over forty states have such a law.

It seems to me well to impress upon you, before beginning any discussion of the medical phase of the law, that the principal parties involved in the act are the employer and employee, that all other factors, the physician, the insurance carrier, the adjustor and the commission are collateral. This necessarily limits us in our discussion to the conditions and facts which are beneficial or detrimental to the employee, employer or both. For that reason, the question of whether the individual physician is benefited personally or injured personally, by the enactment of the law, as far as finances are concerned, has no bearing except as it may affect the employee or employer. This statement could be made with greater force as regards the legal profession, as, I understand, the law deprived them of nearly fifty per cent. of their volume of income. This is an economic law and is for the betterment of the employee and society. On that basis this paper is written. As illustrative of what I mean, I might refer to the increased activities of the state in medicine, especially relative to the contagious and communicable diseases. Its scope has steadily enlarged and probably will continue to do so. As long as commensurate good to the public continues, no amount of argument against the plan, because of its influence on the income of the physician, will bear any weight. So whatever opinions I express or conclusions I draw, they are with that understanding. And further, I do not believe any man can discuss this phase of the law intelligently until he casts aside any bias he may have because of the law. It was not enacted for the benefit or the deprivation of the physician and whatever way the individual physician is affected by it, is purely incidental.

Under the medical section of the compensation law, we shall discuss two questions: first, limited or unlimited medical care, and second, the free choice of physicians.

Before doing this, however, I want to bring to your attention some of the various forms of laws which are now in force in the many states. They are as follows: Limited and unlimited medical treatment, limited and unlimited amounts for services, medical services furnished by the employer, medical services chosen by the employee and paid for by the employer and medical services furnished by and paid for by the employee.

Should the injured employee have limited or unlimited medical aid? Comparing the various state laws, we find that the range of service as regards time is from none in three states up through the two weeks, four weeks, thirty days, eight weeks, sixty days, ninety days and the unlimited period, in the last group there being sixteen states. Limitations as to amount for services range from nothing up to a definite amount of six hundred dollars and into the unlimited. The latest reports that I had access to showed four states which placed no limit as to time or amount. It is interesting here to note that legislation in this respect has been rapidly progressive toward removal of limit.

---

*Delivered before the Broome County Medical Society, February, 1922.

Copyright, 1923, by A. R. Elliott Publishing Company.

From the viewpoint of this law, as an economic one, looking to the benefit of the injured employee and society, as well as the employer, it seems that we are dealing with two forcible arguments, both in favor of removal of limitations. First, it is humanitarian and is demanded by public opinion. Second, the restoration of the injured employee to gainful occupation is essential to society, to industry and the employee. The injured workman receives the greatest good when returned to a gainful pursuit in the nearest to normal condition possible, and compensation paid him, regardless of the amount, is indeed a poor substitute for such restoration. Society and public opinion demand that the number of such derelicts be held to the lowest possible minimum, and finally it is to the interest of the employer, because it reduces labor turnover, maintains a more coordinate working force and in that way increases efficiency, and makes much more valuable the money expended by him for that purpose, than were it spent merely for compensation to the injured man.

We now come to the second question in our paper, which is the free choice of physicians. This will be treated, first, by expressing the arguments advanced in favor of the free choice of physicians, after which will be taken those arguments advanced in favor of the medical services being furnished by the employer.

It will be well for us, as before, to make some comparisons of the various laws existing in different states. In five states the employee is granted the right of selecting his own physician, at his own expense. These are California, Connecticut, Illinois, Missouri and South Dakota. Four states provide, that the employee may choose the physician at the expense of the employer, Massachusetts, Nebraska, Rhode Island and Washington. In Massachusetts the limit is two weeks; unless longer in the discretion of the Commission, Nebraska limits the right to cases of dismemberment and major operations. Rhode Island limits the time to four weeks, and Washington makes a provision that the employee must pay half of the medical cost. Four other states have an interpretation of the law allowing free choice. Twenty states allow free choice, if the employer neglects or refuses to furnish competent medical services, and the rest of the states simply provide for the furnishing of medical services by the employer, excepting the three states mentioned above, which provide no medical aid.

Selection by the employee and paid for by the employer—known as free choice. The reasons advanced for this method are: First, that it has generally been considered an inalienable right of mankind, second, the dissatisfaction with the kind of medical service furnished by the employer, and third, the feeling of the medical profession that the employee should make the choice.

The first reason advanced, that it is an inalienable right of mankind, is of force as regards the relation of doctor and patient in the usual life and activities of communities. That relationship is considered as private and personal, and encourages the development of confidence and faith in the physician. For this reason alone, the free choice of physicians should obtain unless strong and forcible arguments are arraigned against it. Second, the dissatisfaction with the kind of medical services furnished by the employer. As regards this, it does not seem to be a major proposition of the question involved. If unsatisfactory, it does not necessarily imply that it could not be made satisfactory and efforts toward that accomplishment should be instituted. The third reason, that the physicians feel that the employee should have the right of choice is relevant only as it concerns the relief of the injured workman and restoring him to his proper sphere in industry.

As medical men, we should approve the best aid that can be rendered the injured employee which includes early attention to accidents, proper hospitalization for serious cases, and the attention of qualified medical men for different types of injuries. Quoting from a paper, Selection of the Physician under the Compensation Laws, by Dr. John W. Mowell, Medical Advisor, State of Washington. "We often find that a workman who has received a serious fracture will select a man who knows little about fractures; also a man who received an injury to his eyes may go to an ordinary practitioner for treatment until the serious nature of the case makes it necessary to transfer him to an eye specialist, whom he should have consulted in the first place. This occurs more or less with all kinds of injuries." Further "To my mind the principle thing that can be said in favor of free choice of physician by the injured workman is the effect that it has on his mind, that is, the feeling that he is getting what he wants." This is from the medical advisor in a state where free choice exists.

Coming to the selection of the physician by the employer, as opposed to free choice, the following reasons are given: First, the burden of paying for the services rests upon the employer, and it seems reasonable that he should have the choice of selection. Second, he is naturally interested in reducing his compensation costs and, to an extent, this is dependent on the speedy restoration of the injured employee's earning capacity which in turn is dependent largely upon the adequacy of the medical or surgical treatment rendered. Third, that the employer is in a better position and more competent to judge of the efficiency of the physician. Fourth, the inability for the employer to know the following —competency of the physician attending the injured employee, whether unnecessary calls are being made, bills are being padded, prompt receipt of reports and overcharging generally.

The first reason, that the employer pays the bills and should, therefore, have the power of selecting the physician, is nearly an axiom and comes face to face with the reason propounded for the employee selecting the physician—that it is almost an inalienable right of mankind. Both can not be accorded to the respective interested parties and that one must obtain in which more fully meets the fulfillment of the law—the betterment of the injured employee and society. I quote from a paper by Dr. Frederick L. Van Sickle, Does the Two Years' Experience with the Workmen's Compensation Law of Pennsylvania Demand Amendment and, if so, How. "It can not, of course, ever be said that the law is satisfactory, or any law satisfactory which takes away the personal privilege of the employee, the right to select his own physician; and yet from a business standpoint, we can not and must not expect the employer, who is to pay the expense of treating the injured employee, to allow a haphazard method of business to obtain, wherein he has no control of his own expenditure and less control of the entire system upon which he must build his business in order that it may be a success: consequently, none of us must expect that the much advocated plan of the employee selecting his own surgeon can ever be realized."

The second reason is that the employer is interested in procuring efficiency in medical care in order to obtain the speedy return of the injured employee. Illustrative of this is the development in larger plants of the medical service where first aid rooms up to emergency hospitals are maintained together with a complement of doctors and nurses. It is of interest to note that in over fifty per cent. of all injuries there is a disability of one day or less and that less than twenty-five per cent, of injuries extend beyond two weeks. The importance of early medical or surgical attention to injuries is known to you and it likewise has become common knowledge to the employers and insurance carriers. In fact, I venture the opinion that they are more keenly awake to the necessity of it than is our profession generally, because of their intimate knowledge of the results of neglect to obtain early treatment. I now quote from an article by Dr. H. H. Hartung entitled, Medicolegal Phases with Particular Reference to Tort Cases, Compensation and Malpractice Suits. "Prevention is more desirable than the payment of compensation and workers are more desirable than non-workers as they are more valuable to themselves, their employers, and the community. . . . After a certain length of time following the passage of this law (free choice) it was found the best results were not being obtained, and on recommendation of the board the law was changed, requiring the nsurance companies to furnish full medical treatment giving them the privilege of advising them who should treat the cases. There is a very good reason why the insurance companies are interested in this matter . . ." From the employer's viewpoint it s also to be remembered that he was to make an early report of all cases, that he wants dressings made in minor cases early and promptly, with the result that the man's absence from work is as short as possible; this being also to the advantage of the njured, and last, that he can place the responsibility for these things being done on one or a few doctors but would lose all control if the only limit was the number of physicians in the community.

We next come to the third reason, which is, that the employer is better able to select a competent physician than the employee. In considering this phase of the question, I want to bring to your attention several facts. This is a compulsory state law, and, of necessity, equally applicable to all parts of the state. That the smaller locality, the less the choice that exists, and the larger the community, the greater the choice. That the least qualified and the best qualified are found in the largest commuities. In New York State there are 15,213 physiians and of that number 8,729 are in New York City. Also of that number, 15,213, we find in our parent body, the State Society, 9,381, leaving outside of the fold about 6,000. With these facts in mind, is it a question, or does it become a certainty, that the employer is in a better position to choose than the employee, and do so with benefit to the injured workman. Let me again quote from the article by Dr. John W. Mowell, medical advisor to the Commission in the State of Washington. "Under what is known in our state as the State Plan, the law grants the workman the privilege of selecting his own physician in case of injury, provided he resides within a reasonable distance from the injured workman. While this plan seems quite equitable and it appears to be the natural thing to do, it has a good many shortcomings. For instance, to the isolated workman, who is employed in a locality where there are only one or two physicians, free choice means little, and the injured workman has to accept the services of the first physician he can obtain. However, in the larger cities where there is a great number of physicians we find that some of the workmen make a wise choice, while quite a large percentage of them, for some reason or other, select a physician who is not very well equipped for the work at hand." Quoting from an article in the *Boston Medical and Surgical Journal,* June 12, 1919, on Medical Aspects of the Workman's Compensation Laws, by Dr. James Warren Sever, of Boston: "Osteopaths, chiropractors, neuropaths and various other 'paths' are engaged in this type of work, even in Massachusetts * * *. The time is coming, when the state or the insurance company, or both, will select the medical men best qualified to treat these industrial accidents, and when that time comes, the patient will lose through legislative amendment the right to choose his own physician. The right to choose one's own physician is really the decision on the part of the injured workman to treat his own case as he sees fit . . ." This is from a man in a state where free choice exists.

We now come to our fourth reason which really includes several features, all of them aimed at the medical fraternity if free choice was available. The portion of this reason which I shall discuss is the question of competency of the physician. That has been pretty thoroughly covered in the preceding reason and really overlaps it. Referring to the 1916-17 annual report of the California Commission, I quote: "Many poorly equipped medical men are not above accepting industrial cases which they can not handle. The commission feels keenly its responsibility in this matter and, of course, desires that the very best services shall be accorded the injured workingman. * * * The situation constitutes a distinct menace at the present time, and suggests possible failure of the good effects of a most excellent law." The other portion of this reason—unnecessary calls and the padding of bills are outside of the domain of this paper—just as was the reason for the free choice—that the physician feels that the employee should have free choice.

Based on the facts outlined above, I feel justified in the following opinions: That unlimited medical treatment for the injured workman should be provided. That the free choice of physicians is not to the best interests of the employer, the employee and society. This is especially evident when one takes into consideration the opinions of medical departments of commissions and others in those states where free choice exists. That the compensation law is sailing an uncharted sea, as far as precedents are concerned, because it bears no relation to the old employers' liability act under which previously all such cases were tried. That, as an economic law, it is a signal success and denotes a tremendous leap in the direction of progress when compared with the law preceding it. That our efforts should be towards a constructive betterment of the workings of the law as regards the medical section, and this I wish to speak of in more detail.

Having in mind the great percentage of injuries that are slight and have only a short disability, provided prompt attention is afforded, it seems necessary to provide a means of bringing the physician and the injured employee into contact easily. The best solution I know of is the industrial physician and the plant medical department where it is possible for the injured workman to report and be able to obtain immediate treatment. This is analogous to the first aid station or infirmary of the army and as such should rank in the same relative importance. For the small percentage, who have more serious injuries and need more technical care, it is my opinion that they are outside of the realm of the first aid or dressing station and should be sent to the hospital and to men known to be qualified for that type of work. If the physicians engaged by the employer or the insurance carrier treat conditions for which their training and experience has not fitted them, the blame should be placed upon the employer or the insurance carrier who has assumed the responsibility of providing adequate care to the injured employee. I am firm in my conviction that surgery is a specialty and that for such work a man needs training, experience, and time for reading, which is not possible if his time is given up to routine medical practice. The law requires the employer to furnish medical treatment and implies adequate treatment. As I have shown, the law is so framed as to provide a means for the employer to provide medical treatment and that being the case no employee or insurance carrier can evade the responsibility which accompanies it.

In the final analysis the objective of the compensation law is to restore the injured workman as completely as possible. That means that the end result is obtained only when everything possible has been done for the injured employee.

The Variations of the Uric Acid Content of the Blood in Gout

By CHARLES FINCK, M.D.,
Vittel, France.

Since the discovery of sodium urate in the articular concretions of gouty patients by Tennant, 1795, and by Wollaston, 1797, and since Garrod, 1846, demonstrated by means of his thread experiment that the blood in gout contained an excess of uric acid, a paramount importance has been attributed to this substance. Today many authorities dispute its pathogenic significance in gout, though no proof can be advanced that the exclusive cause of the condition rests in the formation, destruction, or excretion of uric acid, nothing, on the other hand, justifies a denial that the substance participates in the evolution of this affection. Whether it is the chief actor or merely a side figure, its quantitative variations in the blood and in the urine of the gouty are of such significance as to deserve the attention which has been attached to them for the last two centuries.

The researches, the results of which are now recorded, were commenced in 1914, when the war interrupted them. My first publications on this question date from 1918; these (1) dealt with the variations of the uric acid content in the blood and urine during a course of the calcium cure. Since then my statements have been verified by Grigaut, Bricourt, and Schneider (2 and 3).

CONDITIONS OF OBSERVATION.

For the study of the variations in the level of the uric acid of the blood (uricemia) and of the urine (uricaciduria) in gouty subjects, I instituted the following precautionary measures: all my patients were submitted to a diet well defined as to quantity and quality. The régime adopted was a mixed diet, the food allowance being determined according to the weight of the patient in such a manner that the number of calories furnished every hour was equal to the bodyweight in kilograms. Twenty per cent. of these calories were supplied in the form of albumins, twenty per cent. as fats, and sixty per cent. as carbohydrates. Meat furnished half of the albumen ration in the form of meat, fowl, and fish, and it was given only during the midday meal. The other half of the protein allowance was supplied in eggs (one a day), in milk and its derivatives, and in vegetables.

The investigations were carried out with serum and not with whole blood. This fact is of capital importance, for the results obtained by the different investigators vary only because some worked with complete blood, while others employed serum. A serum, however slightly tainted, yields results which differ materially from those obtained with a clear serum. The blood was collected by puncturing a vein in the morning before breakfast; the quantity obtained must be sufficient to permit the work to be carried out under the best conditions.

At the outset, I employed the method of Roethlisberger (reduction of silver nitrate to invisibility by a drop of serum on absorbent paper), however, this had to be abandoned, since the results obtained were too inconstant. Next I adopted a combination of the methods of Ruhemann and of Pizzorno (N/100 solution of the iodide and sulphide of carbon), which yielded higher figures than my experience led me to expect. Finally, I utilized the method of Folin, Denis, S. Benedict, and J. Bogert, which is based on the property of uric acid to give a blue coloration with phosphotungstic acid in the presence of sodium carbonate. The method of Grigaut, though based on the same principle, gives somewhat higher figures than the preceding one. On the whole, the latter procedure is the one that seems to me to combine the greatest advantages, such as speed, exactness, and simplicity.

The blood serum of normal persons contains from one to three centigrams of uric acid in the fasting condition, particularly if the food taken on the preceding evening was free from purins. A mixed meal brings about a uricemia amounting to from two to five centigrams during the hours immediately following the intake of the food; however, the previous level is regained in about six or seven hours. Naturally, variations occur according to the nature of the diet and the amount of its purin content.

In gouty persons the position is altogether different. To begin with, the uricemia in the fasting condition is at a considerably higher level, so that readings up to five, six, eight, and even twelve centigrams may be obtained. A further increase occurs after meals, and this is more noticeable than in normal people; above all, it persists much longer. However, in spite of these peculiarities, it regains its initial level after only a short interval. In the course of the evolution of gout the level of uricemia undergoes variations: generally speaking, it corresponds to the duration of the affection. The uricemia noted in young subjects of gout is lower than in the old. It is true, though, that frequently another factor comes into play, namely, renal impermeability resulting from the kidney lesions which determine the onset of gout. However, it must be emphasized that impermeability of the kidneys is not the basis of the uricemia of the gouty. Chauffard, Brodin, and Grigaut have found hyperuricemia in patients with normal renal permeability; this fact a priori eliminates the theory which looks upon the impermeability of the kidneys as the actual cause of gout.

The uricemia of the gouty varies with the incidents which mark the evolution of the disease. The uric acid content of the serum in gout during the periods of acute exacerbations has been the subject of much discussion; while some investigators have found it increased, others report a diminution. These divergences of opinion are due to the fact that the examinations were carried out at different periods in the evolution of the attack. Our researches have demonstrated that the level of the uricemia does not commence to vary until the second or, even, third day after the onset of the exacerbation; by that time, it may amount to a quarter or a third as much as the uricemia measured before the beginning of the attack. Authors who have limited their investigations to specimens of serum collected at the commencement, have naturally had to conclude that the level of the uricemia remained stable; on the other hand, those who carried out their estimations during the period in which the attack developed, recorded increased values. Observations XII and XVI demonstrate the progressive increase during the course of the exacerbation; it amounts to nine, twelve, thirteen centigrams, respectively, on the first, second, and third day in observation XII, and to eight, ten, ten in observation XVI.

As a general rule, the statement may be made that the uricemia is more considerable during acute attacks than during intervening quiescent periods. In observation V it changes from eight to eleven, in observation IX from seven to eleven, in observation XII from nine to thirteen, in observation XVI from eight to ten. After the disappearance of the acute manifestations of gout, provided this has not been brought about by certain therapeutic agents, the uricemia persists for a certain time; later, it drops to a level more or less like the one observed before the attack.

It is clear, therefore, that, contrary to the opinion generally accepted, the acute stage of gout is accompanied by a notable increase in the uricemia, and, furthermore, this increase persists after the disappearance of the acute phenomena of the attack.

The variations of the uricemia have often been attributed to alterations of the chemical reactions of the blood. Here again it has been my aim to control the facts. I have, therefore, investigated the modifications of chemical reactions for uric acid and the serum. Just as in normal subjects, the serum of the gouty is alkaline. The variations of this alkalinity are rapid and extensive; however, the difference between healthy and gouty subjects lies in the fact that the values observed oscillate between different limits in the two groups.

`Expressed in cubic centimetres of a decinormal solution of soda, with phenolphthalein serving as indicator, I have been able to determine the following values for one c. c. of serum: its alkalinity corresponded in the healthy to values which generally oscillated between 1.70 c. c. and 2.40 c. c., and in the gouty between 0.9 c. c. and 1.80 c. c. (Technic: The albumin is removed from the serum by trichloracetic acid. To two c. c. of this serum a few drops of a solution of phenolphthalein are added. Into this mixture decinormal soda solution is then dropped, until a persistent rose coloration has been obtained. The number of N. of c. c. employed is noted. In similar manner one c. c. of the solution of trichloracetic acid is treated, and the number of N′ of c. c. of decinormal soda solution utilized is noted. It is obvious that the alkalinity of one c. c. of serum is represented in c. c. of the decinormal solution of soda by the difference N-N′.)

It follows, therefore, that gouty serum is hypoalkaline during the intervals between attacks as compared with the serum of healthy subjects. This fact is of considerable interest and deserves to be remembered, for hypoalkalinity of the serum is not encountered in the uricemia observed, for instance, in cases of nephritis. Observation VI is a remarkable proof of this difference: a uricemia of 0.14 corresponds to an alkalinity of 2.3, that is, a normal alkalinity. The majority of authors hold the view that the alkalinity of the blood diminishes during the evolution of an attack of gout. Pfeiffer, Jeffries, Drouin, and Luff, on the other hand, have shown that this alkalinity increases. My own observations are in conformity with those of Luff; in all instances I was able to demonstrate an increase in the alkalinity at the commencement of the acute attack. It may suffice to refer to observations V, VIII, IX, XII, XVI. At the same time I have observed that serum taken from gouty patients during the acute stage can still dissolve uric acid; this is a fact which invalidates the view that the blood becomes saturated with uric acid at the moment the attack commences. After the exacerbation subsides, the level of the alkalinity of the serum remains above the values observed before the attack and this condition persists for varying lengths of time.

Observations V and IX plainly demonstrate that the level of the alkalinity of the serum varies with the uricemia. In observation V a uricemia of 0.08 goes together with a serum alkalinity corresponding to 1.2 c. c. of a decinormal solution of soda for every c. c. of serum, whereas a uricemia of 0.11 corresponds to 1.7 c. c. of a decinormal solution of soda expressed in the same terms. To a uricemia of 0.97 corresponds an alkalinity of 1.4 in observation X; and to a uricemia of 0.11 corresponds an alkalinity of 2.1. For this reason our second conclusion states that the acute stage of gout is accompanied by an elevation of the alkalinity of the serum.

By preparing the variations of the uricemia with the alkalinity of the serum, it is found that the level for the two values varies in the same direction, i. e., the uricemia increases and decreases with the alkalinity of the serum; however, there exists no proportional relationship between the oscillations of these two characteristics.

Starting with these findings, it was thought of interest to determine whether the intake of alkalies or of acids modified the level of the uricemia. The repeated consumption of alkalies does, in fact, increase the uricemia, as I have demonstrated in 1918 by describing the mode of action of calcium sulphate waters, and these findings have since been confirmed by Schneider. The alkalies must therefore be considered to favor the onset of acute attacks of gout. The supervention of acute exacerbations in the course of the alkaline treatment is by no means a rare occurrence, and physicians practising at alkaline stations have frequent opportunities to verify the truth of this remark. The proof of these facts may be found in observations VIII, IX, XVIII. I have witnessed the uricemia of a patient subjected to the alkali cure increase from 0.07 on the fourth day to 0.15 on the twelfth day.

The frequent administration of phosphoric acid (Joulie's treatment) exercises an influence on the uricemia which is diametrically opposed to that caused by the alkali treatment. We have noted that patients who have been submitted to this treatment for some time, have declared that since the commencement the attacks have become less frequent; on the other hand, however, several of them noticed an increase in the size of their tophi. The examination of the blood serum in these cases has shown that the average level of the uricemia was neither above nor below that of other gouty subjects, only the alkalinity appeared to be more or less diminished. The figures obtained are among the lowest I observed (observations X and XI).

There still remained the task of studying the variations of uricemia under the influence of an heroic gout remedy—colchicum. On the same occasion I recorded the results obtained in two cases of acute exacerbations of gout treated by subcutaneous injection of the fluid taken from blisters.

Among all the numerous drugs used in the treatment of gout, colchicum stands highest in the favor of the patients. If it is taken at the beginning of the attack, it stops its development, arrests the painful, inflammatory swelling, and brings immediate relief. Colchicum also instantly stops the increase of hyperuricemia, usually noticed at the onset of the exacerbation, but, on the other hand, it only slightly modifies the alkalinity of the serum. The patient in observation VIII had a uricemia of 0.12, during the period of the attack, with an alkalinity of the serum corresponding to 1.8 c. c. of decinormal solution of soda after treatment with colchicum extending for three days. The attack left only a slight amount of discomfort; while the level of the uricemia fell to 0.07, the serum alkalinity remained at 1.9.

I have treated a certain number of cases by means of subcutaneous injections of the fluid from blisters, thus administering a kind of autoserotherapy. The following is a description of the method: As soon as the first symptoms of the acute attack appear, a blistering agent, calculated to yield about five c. c. of fluid, is applied to the patient. The swelling is then punctured, under all aseptic precautions, with the needle of a syringe, and the fluid, thus collected, is injected under the skin. By this method it is often possible to arrest the development of an acute attack. Moreover, if the level of the uricemia is examined at the same time, it is found that it has regained its original level after having commenced to rise at the onset of the attack.

Observations V and XIII give a record of two cases of this kind. In observation V the hyperuricemia, which had reached 0.11, has dropped to 0.09, and the alkalinity has similarly receded from 1.7 to 1.5. In observation XIII the hyperuricemia has fallen from 0.13 to 0.08, while, on the other hand, the alkalinity has only varied slightly, namely from 1.4 to 1.2.

Thus it has been shown that colchicum and the subcutaneous injection of fluid from blisters arrest the attack of gout and force down the level of the uricemia. However, while in other cases the variations of the uricemia are accompanied by changes in the chemical reaction of the serum, this does not occur to any morked extent in the instances under review. It appears that such changes do not take place with the same regularity as in the cases recorded above.

CONCLUSIONS.

The gouty person is in a condition of permanent hyperuricemia, the degree of which is still further increased at the onset of the acute attack.

The alkalinity of the blood is diminished in the gouty, but it increases at the beginning of the exacerbation. The excretion of uric acid increases during the attack: in some cases to a very marked extent, in others in a less pronounced manner.

In the latter case, on the other hand, a considerable increase in the excretion of urea takes place. The use of alkalies raises the uricemia, while acids diminish it. The former favor the production of acute exacerbations, the latter reduce their frequency.

Colchicum, administered at the beginning of the attack, arrests the characteristic feature, the increase of hyperuricemia, and, at the same time, it reduces the urinary excretion of uric acid.

These facts are in opposition to the conception held up to the present, that exacerbations of gout are the vivid manifestations of the precipitation of uric acid in the tissues.

In fact, if the attack were of this nature, the uricemia would not increase with its development, on the contrary, instead of increasing, the uric acid content of the body fluids would actually diminish, were they to rid themselves of their abnormal burden by discharging it into out of the way tracts of the organism.

If the attack corresponded to the saturation of the body fluids with uric acid and the albuminoid substances, which are found together with it in the blood of gouty subjects, the serum of gouty patients would be incapable, during the attack, to dissolve further amounts of uric acid. This, however, is not the case.

If colchicum stops an attack of gout by stopping the increase of hyperuricemia, one of its characteristics, this proves that the exacerbation is accompanied, not by a precipitation, but by a resorption of uric acid.

Perhaps it may be suggested that the formation of tophi after an attack of gout is in opposition to my conclusions. In reply to this, I would point out that the formation of tophi often occurs in the absence of acute exacerbations, that they almost always improve with the onset of the attack, and, finally, that they frequently disappear after a pronounced and violent attack.

The progressive increase in the size of articular tophi after successive attacks is due to the local inflammatory reactions which determine the rapid resorption of gouty deposits. In any case, it must be kept in mind that joint tophi contain considerably larger amounts of calcium carbonate and phosphate than uric acid. It is the lesions due to osteitis which bring about the formation of tophi, and, if they increase after every attack, it is not due to the arrival of fresh supplies of the socalled gouty substance, but to a new outbreak of osteitis.

Although it is clear that alkalies favor the cessation of an attack of gout, it is not possible to state that the production of an attack depends exclusively on the reaction of the tissue fluids.

Other causes of circulatory and nervous nature must be reckoned with. Thus the study of the oculocardiac reflex has revealed to me that all gouty subjects are, so to speak, sympathicotonics. Perhaps the etiological factors of gout will be found in the pathology of the sympathetic sytem. What I desire to demonstrate in the present paper, is the fact that the acute attack is a phenomenon of absorption and not of formation of gouty deposits.

The Treatment of Precancerous and Cancerous Lesions in the Mouth*

By WILLIAM H. SCHMIDT, M.D.,
Philadelphia, Pa.

While cancer in the oral cavity is very accessible and readily recognized in its early stages, it is one of the most fatal forms of cancer, and its treatment, up to the present time, has not been well directed. The ultimate mortality has been maintained by temporizing with small but fully developed lesions, the extravagant sacrifice of tissue in mild cases, and frequently the patient is allowed to succumb with no treatment at all. Distant metastasis is infrequent, the disease seldom breaking through the lymphatic collar of the neck, thus giving a greater opportunity for treatment of these conditions.

If we want to improve our cancer statistics, we must recognize the great importance and significance of precancerous lesions, and direct our attention to their removal before they have a chance to become dangerous. The onset of cancer is insidious and accompanied by few and unimportant symptoms. It is generally recognized that the majority of cases start as apparently innocent benign lesions, and that the transition into the malignant stage occurs very insidiously. It is the chronic, continuous irritation and not the acute injury that is the starting point of cancer and any lesion, no matter how innocent it may appear, if subject to or producing irritation, may, in a susceptible person, quietly undergo a malignant change before the seriousness of the condition is realized. Therefore, we must consider primarily what these precancerous lesions in the mouth are and what form of treatment is best adapted to their eradication.

Leukoplakia is one of the most common forms of precancerous lesions in the mouth and is itself frequently the result of some irritation. It may develop slowly or acutely. I have seen a patch of leukoplakia develop rapidly as the result of a sharp tooth rubbing the tongue. At other times, it is the development of months or years. The relation of syphilis to this condition has been much debated, but careful investigation has shown that the greater percentage are not associated with syphilis and only twenty-five to fifty per cent. of cases have shown a positive Wassermann, as reported by different authorities. A large percentage of cases give a definite history of excessive use of tobacco and, as a rule, in these cases the lesion is widespread and includes considerable mucous membrane. Chewing tobacco would appear to be a more likely cause than smoking, especially when the quid is always held in the same location in the mouth. Rough or diseased teeth by their mechanical irritation initiate the disease in the great majority of cases, especially where they come in contact with the cheek or tongue.

The earliest change in the mucous membrane is an inflammatory process with secondary hyperkeratosis. As the disease progresses, there is increased hyperkeratosis so that the papillæ become obliterated and an inflammatory infiltration of the cornium with small round cells takes place. A small white patch is the first evidence which, as the disease progresses becomes pearly or milky white and shows thickening and infiltration. At times, the patches become quite thick and indurated suggesting a malignant change. Prompt and careful treatment should be the rule, and the first thing is a thorough cleansing of the mouth. All sharp and decayed teeth should be removed, and the use of tobacco interdicted. This may suffice to clean up some cases. For the established lesions several forms of treatment have been suggested. Antisyphilitic treatment has no effect on the established lesion. Röntgen ray treatment is difficult and as a rule useless. Radium has been successfully employed and in certain cases is to be preferred, but the technic must be correct and exact.

Destructive treatment has been the most successful. The actual cautery has been used for this purpose but is not recommended because you can not accurately control its action, and the resulting scar is frequently as dangerous a source of irritation as the original leukoplakia. The use of the high frequency current for its destructive effect is ideal because we can accurately control its effects, the technic is easy and the healing takes place with a soft pliable scar which is almost a regeneration of the healthy mucous membrane.

The currents used for this destructive effect are high frequency currents but vary in voltage and amperage, and each has its own particular use and indication depending on the nature and the extent of the tissue to be destroyed.

The current is obtained from the high potential coils where the commercial current, either direct or alternating is transformed by means of a coil and leyden jars into a current of high potential and frequency. The Oudin current is the one most frequently used for destruction of areas of leukoplakia and all smaller growths, and is of relatively high voltage and low amperage. Only one wire is necessary for the employment of this current. It is capable of accurate regulation, and we may obtain a current so fine that it may be used on the cornea of the eye. This current simply dehydrates the tissue thus destroying it, and has therefore been called the desiccating current.

Where more powerful effects are desired, we employ the D'Arsonval current which is of low voltage and very high amperage and thus produces a great amount of heat. This current must be employed with two wire or bipolar and is used for destruction of large growths. We use a large pad on some indifferent part of the body as the inactive pole, and a needle point as the active pole. The effect of this current is more of a coagulation, but without carbonization, and has been designated electrocoagulation, or high frequency cauterization. While there is no selective action on malignant tissue, the current is driven in with such high voltage that it produces heat well beyond the area actually destroyed. Cancer

---

*Read before the Lycoming County Medical Society, Cancer Day, November 10, 1922.

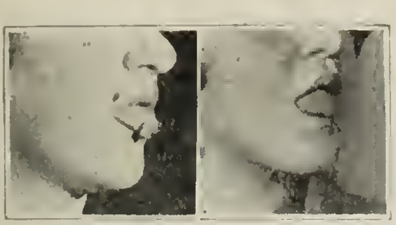

FIG. 1.—Fibroma of tongue. Three years ago a small pimple appeared on tongue, growing rapidly the last few months. Was pedunculated and hard, giving no pain. Easily removed by electrothermic method. Frequently a precancerous lesion.

Second illustration shows results of electrothermic removal.

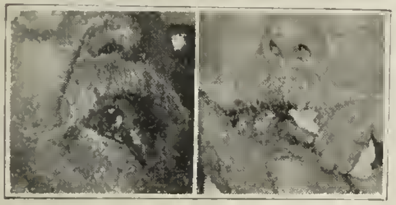

FIG. 2.—Six months ago patient noticed sore throat and a small wart on side of tongue. Last few weeks has grown rapidly. No pain. Ulcerated growth size of quarter, slight induration. No. glands palpable. Pathological report epithelioma. Destroyed by electrothermic method and radium applied to neck.

Second illustration shows result after treatment.

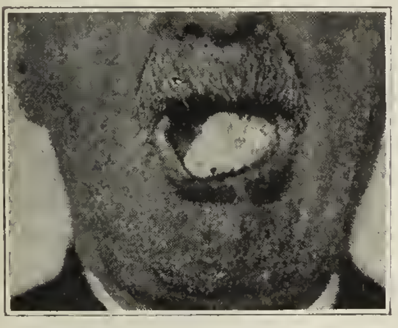

FIG. 3.—Extensive leukoplakia of the tongue. Began as a small white spot three years ago, and has grown rapidly in last six months. Now very thick and indurated. Character of lesion which eventually ulcerates and becomes malignant. Removal of the lesion by the electrothermic method in the early stages prevents cancer.

cells are known to succumb to a less degree of heat than normal, and thus we get devitalization of cancer cells well beyond the area actually destroyed. These currents are all subject to great regulation as to the heat produced which may vary from a simple hyperemia to actual carbonization. We are thus enabled to obtain a current suitable for each case depending on the size and location of the growth to be destroyed. As leukoplakia is as a rule a superficial lesion the Oudin current is employed and with careful technic, the diseased mucous membrane can be removed with very little effect on the healthy tissue, and the healing which follows is all that could be desired.

Ulcers are a frequent precursor of cancer and are of four varieties; simple, tuberculous, syphilitic and malignant.

Any ulcer in the mouth which does not show decided healing after two weeks' time, and after any exciting cause has been removed should be regarded with great suspicion. If there is any one thing more harmful than another in the treatment of an ulcer of the mouth it is the application of strong caustic. A simple ulcer may thus be made malignant, and a malignant one stimulated to more active growth. Simple ulcers are, as a rule, due to the mechanical irritation of a sharp tooth. They are shallow and have no indurated edges and on removal of the cause promptly heal.

Tuberculous ulcers are usually associated with tuberculosis of the lungs. The edges are sharp cut, undermined and everted, and the ulcer is usually quite painful—they heal slowly or not at all.

Syphilitic ulcers may be in the form of a chancre with its classical symptoms or a brokendown gumma. The latter is usually multiple, deep with excavated and uneven edges, some infiltration and considerable discharge. The glands, if involved, appear early in the disease. Differential diagnosis is very important as the resemblance to cancer is often close, and it would be unfortunate to sacrifice important structures needlessly.

When properly diagnosed antisyphilitic treatment promptly heals them, but it is well to remember that we frequently have syphilis and cancer associated in the same lesion. Any of these forms may become malignant, and if after appropriate treatment for two weeks there is not a decided improvement, they should be regarded with suspicion.

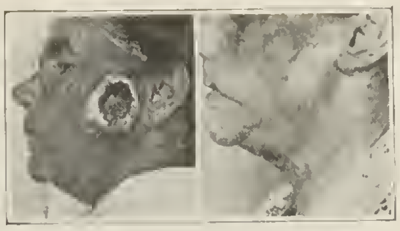

FIG. 4.—In April, 1919, small wart appeared on face. Month later, doctor tied a string around it. Began to grow again very rapidly until large ulcerated mass resulted. Entire cheek infiltrated, including the mucous membrane. No glandular involvement. In November, patient treated by radium needles buried one inch apart covering entire growth. Radium plaque applied to neck. Only one treatment was given.

Second illustration shows result after healing. Part of facial nerve was destroyed. Cheek is soft and free from disease almost four years.

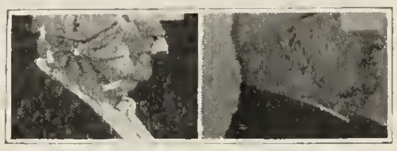

FIG. 5.—Malignant involvement of the glands of neck beginning two years after surgical removal of carcinoma of cheek. No recurrence at local site. Showing method of applying radium needles. Especial attention being paid the margins. Had this case received radiation at the time of operation, this condition would probably have been prevented.

Results after healing shown in second illustration. Complete disappearance of malignant tissue. Neck is soft and free from disease.

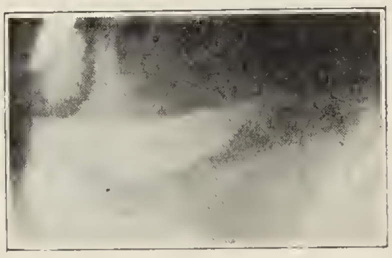

FIG. 6.—X-ray of mandible showing sequestrum formation after treatment of the jaw bone for malignant disease with the electrothermic method. Sequestrum usually separates in six to eight weeks after treatment.

An unfortunate procedure is the taking of a section and waiting a week or two for a report. Blood and lymph spaces are thus opened and the growth stimulated. In any event, if the ulcer is in question, regardless of its nature, simply syphilitic, tuberculous or malignant, its total eradication is indicated. This may be done surgically, but in the author's experience, the ideal method is the use of electrocoagulation which produces a complete destruction and seals the blood and lymph channels at once. Healing is prompt and the resulting scar is soft and pliable and does not form a further menace to the patient. This result is obtained in either simple or tuberculous ulcer, and in the syphilitic type when combined with specific treatments.

Rough or decayed teeth are a frequent and dangerous source of irritation. Sharp edges of a tooth will frequently cut into the tongue or cheek producing an ulceration, which, if not eradicated, will eventually undergo a malignant change. Decayed teeth, pyorrhea and tartar formation around the roots also cause a chronic irritation which frequently leads to malignancy. Badly fitting dental plates, or bridgework, are occasionally found as exciting causes of cancer. The proper treatment is thorough cleanliness and correction of dental defects. It is rare indeed to find cancer in a clean mouth.

Tobacco, unquestionably, acts as an irritant, and fully ninety per cent. of men with malignant disease of the mouth have a history of excessive use of tobacco. Nicotine is a decided irritant and when the heat of a pipe or cigar is added, this continuous irritation is just what is needed to produce a malignant change. Frequently, the first stage is a leukoplakia, as has been mentioned, and there can be no question but that tobacco is a very decided factor as an exciting cause of cancer.

While syphilis itself does not have a direct bearing on cancer, its indirect effects are important in preparing the tissue for a malignant change. Cancer may devolop in the scar of a healed syphilitic lesion even years later, while active lesions such as an ulcer, gumma, papilloma, or atrophic glossitis are commonly seen as exciting causes. Cancer and syphilis may both be present at the same time. If a correct diagnosis of syphilis is made, the lesion should heal promptly under antisyphilitic treatment. If it does not heal, the lesion should be removed as the chances are very great that we have a malignant lesion associated with the syphilitic one, and valuable time will be lost in temporizing with such a condition after a reasonable length of time has elapsed. Most of these lesions can be easily removed by the electrothermic method.

There are a number of more uncommon causes of irritation in the mouth, one of which may be mentioned, namely, angiomata. These may exist for years without causing trouble, but if for any reason, they are subjected to continued trauma, they may undergo a malignant change. Simple papilloma is seen not infrequently, and occasionally a salivary calculus may be the cause of trouble. Other causes are the use of snuff, or carrying tacks or nails in the mouth, as is the practice of certain workmen. All of these conditions should be eradicated as soon as possible.

It can well be seen that our first duty is the elimination of every possible source of irritation, and if the physician would consider this seriously, we would soon diminish the number of cases of cancer in the mouth. The easiest and best way to cure cancer is to prevent the development of the lesion, and not by extensive operation after it is fully developed.

Cancer of the mouth is always of the most malignant nature, infiltrating the tissue rapidly and involving the glands early. If the lesion has been present for six weeks or more, it is quite likely the glands are already involved, although this is not always the case. We must therefore realize the vast importance of early treatment, because if the glands are already enlarged, the chances of cure are very materially lessened. The local lesion very seldom causes the death of the patient but metastasis to the glands finally carries them off. It is bad practice to take a section for pathological study and wait a week or more for a report. Provision should be made for immediate examination of a frozen section at the operation, and then proceed at once in cases where it is pronounced malignant. The submaxillary and the submental glands are usually the first involved, followed by the superficial and deep cervical glands. An important fact to remember is that the anterior part of the tongue, and the floor of the mouth and lower lip, have a direct connection with the deep cervical glands, and the latter may be involved while the superficial glands are free. In an ulcerated lesion, the glands may be enlarged from a simple infection, but as a rule, it is not difficult to distinguish a malignant gland. It is very hard and usually adherent to adjacent tissue while the infected gland is doughy in feel and very tender.

Cancer of the tongue is one of the most distressing conditions the physician is called upon to treat, and a whole volume might be written on this subject alone. It may develop as an ulcerated destructive lesion, or as a simple induration in the muscle. It is frequently preceded by leukoplakia or other precancerous lesions which undergo a malignant change. The ulcerated lesion is superficial at first, and as it progresses, it becomes deeper, leaving the edges prominent and hard and showing an infiltration extending well beyond the margin. It is as a rule not very sensitive, and does not cause pain until well advanced. The first sign of pain and frequently the only symptom present is pain in the ear. At times, the patient is treated for earache or some dental irritation, and valuable time may be lost before the true nature of the condition is discovered. Later as the condition advances, there is considerable sloughing with frequent spells of bleeding, a malodorous, purulent discharge and severe pain. The infiltration increases and the tongue becomes fixed. The glands are enlarged, adherent and painful.

The most frequent spot for the lesion to appear is on the side of the tongue where it comes in contact with the teeth; another frequent site is the tip of the tongue and lastly the base. Cancer of the tongue is nearly always squamous cell carcinoma arising from the mucous membrane of the tongue, or the epithelial cells of the glands. Lymphatic vessels go to either side of the neck so that frequently the opposite side of the neck is involved. The deep cervical glands are frequently involved even where they are not palpable. If the growth has encroached on the floor of the mouth, the prognosis is very unfavorable.

TREATMENT.

Realizing the malignant nature of the condition, it is apparent that early treatment is essential. Various methods of treatment have been recommended. The surgical operation is usually a serious and shocking procedure and subject to the dangers of postoperative infection and pneumonia with from twelve to fifteen per cent. five year cures.

Radium is used, but to my mind it has an extremely limited field in this condition. Surface applications of radium are absolutely useless and may be dangerous, as they heal over a lesion leaving active disease beneath. The only course justified is the use of radium needles, and to this there are very serious objections.

It is difficult to estimate the right dose to secure action on the entire tumor mass, and the pain after treatment is very severe and lasts for weeks and sometimes months. The resulting scar is dense and hard, and it is impossible to say after the reaction whether the disease is still present, or whether the induration is simply due to scar tissue formation. At other times, we have a foul indolent slough which lasts for weeks. The suffering and discomfort is not justified if we have a method without these objections, and with superior results. If the operator desires to use embedded radium for its crossfire effect on the floor of the mouth, the lesion should be destroyed by the electrothermic method, about one week after the radium treatment and before the radium reaction has set in with full force and in that way most of the objections are removed. The x ray has absolutely no effect on this condition.

Experience has shown that the electrothermic method is by far the most satisfactory way of treating the local lesion. The control is such that we can destroy an ulcer with its surrounding induration without doing an extensive operation, or we may remove the entire tongue. In the latter case, a general anesthetic is given, and after the patient is thoroughly anesthetized, the ether is removed from the room as otherwise it would be set on fire by the spark. The mouth gag is then put in place and a suture run through the tongue. The tongue is drawn forward, and with a curved needle employing the D'Arsonval current, a line of coagulation is made across the base of the tongue. The tongue is then raised, and with a straight needle a line of coagulation is made under it and to the sides. With this current, the needle is plunged into the tissues to get deep penetration and greater destruction. Then with scissors, we cut through the coagulated tissue stopping when half way through for another application of the current to make sure coagulation has extended through the tongue. The tongue may then be entirely freed by cutting with scissors through the coagulated area, without the loss of a drop of blood. The base is then gone over with the current and again thoroughly coagulated. The coagulated area is allowed to separate as a slough which takes about a week. The patient suffers little shock, and the next day is up and out of bed. There is considerable swelling of the neck for two or three days, but very little pain. I have never seen infection follow and exceptionally a secondary hemorrhage, which usually occurs in patients with high blood pressure. There has been no operative mortality so far. Bleeding is most likely at the time of separation of the slough, but if proper care is taken, it is very unlikely to occur. Almost invariably the local condition heals up without evidence of disease except where the floor of the mouth is involved, when good results are not so easily obtained.

The advantages of the method is the complete destruction of all cancerous tissue at once, regardless of whether the lesion is small or involves the entire tongue, and absence of bleeding, shock, infection, or severe postoperative pain. At the end of two or three weeks' time, we can tell absolutely whether we have destroyed all disease or not, and if a diseased area remains, it can be treated at once. With proper experience, the local lesion can usually be eradicated at one sitting, and a healthy soft scar results after healing. If the glands are not already involved there is less likelihood of spreading the infection, as all blood and lymph spaces are sealed at once while surgery or radium needles cut into the lymph vessels. To one who has had experience with the electrothermic method its superiority is beyond question, and results which will be reported later will bear out this statement.

Success or failure in a case depends entirely on the glands as it is the glandular metastasis that kills the patient. The lymphatic glands act as a barrier to prevent the spread of the disease, and if they are not enlarged a block dissection should not be done. If extension takes place from the local lesion to the glands, it must travel by way of the lymph vessels either by direct lymphatic extension or by embolism, and if the glands are removed, these vessels drain into the tissue of the neck and thus infect the neck. Every case, regardless of whether the glands are enlarged or not, receives thorough radiation of both sides of the neck. The neck is marked out in small squares about twenty-four in number and to each one is applied fifty mg. of radium in a 0.5 mm. brass filter and separated from the skin by half an inch of gauze, for a period of four hours, making a total of 4800 milligram hours. This is repeated twice at six week intervals. If the glands are already enlarged more drastic treatment is necessary and we bury radium needles into the substance of the gland. These needles are about one inch in length and about the size of an aspirating needle. They are hollow and contain ten mg. radium. One end has a sharp cutting edge and the other end has the eye which is threaded with heavy silk. They are allowed to remain in the gland twenty-four hours after which they are withdrawn by means of the thread. From one to five or more needles are used depending on the size of the gland. and except for some very special reason this is not repeated. These cases receive in addition, the surface application of radium or heavy doses of x ray. If a single gland is enlarged it may be removed, and this is usually done about two weeks after radium treatment. In this way, we feel that all indications have been met to the best advantage and the patient given the greatest chance to overcome the disease.

Cancer of the alveolus usually begins around a decayed or rough tooth. At times, there is advanced pyorrhea or leukoplakia. Frequently, a tooth of this kind will be extracted and the gum does not heal, thus calling attention to the fact that something is wrong. At other times, the first thing a patient notices is a loosened tooth. There is seldom any pain. Examination shows an ulcerated urea, or a soft spongy bleeding gum with a malodorous discharge. The first thing to do in these cases is to make an x ray examination of the jaw bone to see to what extent it is involved. Only the margin may be involved or the disease may have extended half way through the bone. Examination of the glands will usually show the submaxillary gland enlarged, hard and adherent to the bone. Pain is usually absent until later.

Again, early treatment is most important. The surgical operation calls for complete resection of the jaw well beyond the diseased area with block dissection of the glands. This has been the only treatment in the past and was successful in a good percentage of cases, but left a marked deformity of that side of the face.

Fortunately, the electrothermic method will destroy the bone as well as the flesh, so that this form of treatment has a decided advantage over surgery in that we can destroy the diseased tissue with the current and then apply it to the bone, devitalizing and destroying only that part of the bone which is diseased. In this way, the healthy bone is allowed to remain and maintain the outline of the jaw. The devitalizing bone is allowed to remain and it sequestrates in about six weeks. I have seen cases in which not more than one eighth of an inch of bone has remained to support the jaw. This method is particularly valuable where the disease crosses the midline in front, because if this part of the bone is removed there is no support for the tissues ot the mouth and the patient is in a very deplorable condition. In these cases, the glands are most important, and careful attention must be paid to them, if we hope to get the patient well.

Epulis is of two varieties, the first being the hard fibrous tumor classified as fibrosarcoma. It is slow in growth and seldom produces symptoms, and if totally removed does not recur. The second variety is soft, vascular, grows rapidly and involves the bone. It is malignant and requires radical treatment. Both varieties are very satisfactorily treated by the electrothermic method. The growth is destroyed, the adjacent teeth removed and the bone treated well beyond the diseased area. Results have been very satisfactory.

Cancer of the floor of the mouth is usually secondary to cancer beginning in the tongue or alveolus and extending to the floor of the mouth. Occasionally, we see it primary in this location where it may be the result of a salivary calculus, a foreign body as a fish bone, or some other irritation. It usually starts as an indurated ulcer and is always serious, involving the gland early and infiltrating the tissues rapidly. Surgery is not very useful in this condition, and as a rule, we have to combine the electrothermic method with radium. The ulcer and all microscopic diseased tissue is destroyed with the current and curetted away. The base is then thoroughly gone over with the current, and radium needles are buried in the tissue about an inch apart all through the diseased area and allowed to remain from twelve to twenty-four hours. Again, careful attention must be given the glands in each case, and appropriate treatment, directed to destroy or control the disease present.

Cancer of the cheek is much more common than generally supposed, and occurs mostly in the posterior angle of the mouth, and around the opening of Steno's duct. In the early stages, we may have an ulcer resulting from a rough tooth, or a simple wrinkling of the mucous membrane with superficial induration. This eventually breaks down and ulcerates and infiltrates the tissues. At other times, it starts from a patch of leukoplakia. Almost invariably this condition is well advanced before a physician is consulted, due partly to the fact that there is no pain. The electrothermic method is indicated in this case, and we may destroy the growth completely without going through the cheek. The coagulated tissue is curetted away, and the base thoroughly sealed by the current followed with appropriate radium treatment to the glands, and frequently we must bury radium in the margins of the lesion after destruction with the current, as the disease is usually malignant in this location.

Cancer of the tonsils is a rapidly spreading and deadly disease. The symptoms are mainly a sore throat continuing over a long period with development of an indurated ulcer. The pillars are quickly involved and the glands show disease almost from the beginning. Because of the close proximity of the large vessels, the electrothermic method can not be used and surgery is frequently a difficult proceeding. The best results are obtained by use of radium needles in appropriate number and dose followed by thorough treatment of the glands as has been indicated. If possible, surgical removal of tonsils may be done first, followed by implantation of radium in the surrounding tissue.

Cancer of the antrum is usually an extension from a growth on the upper jaw. A decayed tooth is usually the starting point, and the disease soon extends into the antrum itself. Occasionally, we see this condition primary in the antrum. Every case of cancer in the upper jaw should be x rayed to determine the condition of the antrum, as frequently there are no symptoms to suggest it. The longer the condition exists, the more likelihood of the bone being diseased, and occasionally the disease involves the orbital plate and even breaks through into the orbit. It may also invade the ethmoid cells. Radical treatment is necessary and the surgeon would have to remove the entire maxilla, which is a serious and deforming operation. On the other hand, the electrothermic method may be used and the contour of the face preserved. The disease of the upper jaw is destroyed and a long sharp needle is used to carry the current into the antrum. The needle is inserted well up into the antrum and a strong current used until all the contents of the antrum are coagulated. Then the edges of the bone are removed with rongeurs and with a large curette the entire contents of the antrum are removed. There should be very little bleeding, but if it is excessive, the antrum is packed for a short time and then the remaining tissue is treated. Care must be had lest the orbital plate be destroyed unless it is already diseased. As a rule, we pack the antrum for a few days. It is also advisable in these cases to place a capsule of radium in the cavity for twenty-four hours. In a week to ten days all slough is usually loosened, and in six weeks all devitalized bone comes away. Healing takes about eight to ten weeks. This leaves a large opening into the antrum, but a properly fitting dental plate can be made with a pad to fill up the antrum and the results are very satisfactory. These cases are treated successfully, because, as a rule, there is no glandular involvement, unless the condition has been neglected. Occasionally the disease breaks through into the face. In this event, it is better to destroy the disease through the face under the eye as it gives better access and increases our chance.

Cancer of the lower lip is of frequent occurrence and is of a malignant nature. There is no reason why these cases should not be treated early, as the patient is usually aware of the lesion almost from the beginning. Yet, it is astonishing how people will neglect treatment until the condition has become a serious matter. The glands usually become involved early, although we do see cases which have existed for months without apparent glandular involvement. The first sign of trouble may be a dry scaly spot which may exist for months, but eventually it begins to infiltrate and later a small ulcer will appear. This frequently heals only to open again. It is at this stage, or before, that we should treat the condition and not later when the infiltration is deep and the ulcer breaking down with the gland already palpable. At other times, we may have a cracked lip which does not heal, a fever blister which remains, a spot of leukoplakia or a sore from a pipe or cigar. We must educate the laity that this is the time to seek treatment, if we hope to accomplish any improvement in our cancer statistics.

Once the lesion is fully developed, we may have an ulcerated indurated sore involving a small or large extent of the lip. Another form is the fungoid type where the malignant tissue grows outward. Infiltration may extend down the lip a considerable distance. If the corner of the mouth is involved, it is usually much more malignant and grows rapidly.

The surgical treatment involves removal of a wedgeshaped or square piece of the lip going well beyond the diseased tissue and with block dissection of the gland on both sides of the neck. At the present time, many surgeons do not look favorably on primary removal of the glands whether they are involved or not. The glands are nature's safeguard or filters, and if extension to the glands takes place the lymphatic vessels must carry the disease. Therefore, if the local lesion is removed and the glands also, what becomes of the disease in the lymphatic vessels? It drains into the tissues of the neck and the wound breaks down, as I have seen in several cases following operation. Something more than surgery is necessary, if we wish to be thorough Experience in a large series of cases has shown that a combination of the electrothermic method, radium and x ray will cure a large percentage of cancers of the lip where the glands are not already involved, and give far better results than any other form of treatment when the glands are involved. The technic is as follows: Because of the anatomical structure of the lip it lends itself readily to the use of local anesthesia, and accordingly we use a two per cent. solution of novocaine and infiltrate well beyond the diseased area. The local macroscopic disease is then thoroughly coagulated with the current, and in this way, we seal the blood and lymph spaces at once, and the intense heat penetration devitalizes certain cancer cells which may be just beyond the area actually destroyed. The coagulated mass is then cut out with scissors and without bleeding. The base is then gone over and again thoroughly treated with the current. The entire lip and neck are now marked out in squares about one and a half inches in size and a fifty mg. tube of radium on a half inch pad of gauze applied over each area for four hours. This latter is repeated in six weeks, and again six weeks later. If the glands are already involved, we bury from one to five radium needles in each gland and allow same to remain for twenty-four hours. This as a rule is not repeated.

By this technic, we have removed the local lesion, sealing the blood and lymph spaces, treated the lymphatic vessels in the lip and neck with radium and given appropriate treatment to the glands. It would seem, in this way, that all indications have been well met.

Cancer of the mouth is a large subject and has only been superficially treated in this paper, but it can well be seen that no one method of treatment will suffice for all cases, and to obtain the best results, we must use a combination of methods selecting those which in each case seem to meet the indications best.

In conclusion the following should be emphasized:

1. Removal of precancerous lesions of the mouth is the most important factor in the fight against cancer.
2. Early and proper treatment of cancer is essential for success.
3. No one method should be used for all cases, but a proper selection in each individual case, and more often a combination of two or more methods.
4. Many cases, previously considered hopeless, are now amenable to surgery, x ray, radium and the electrothermic method, either alone or in combination.

Medical Arts Building.

Hypermyotrophy of the Uterus (Reinicke)

By WILLIAM EDGAR DARNALL, A.M., M.D., F.A.C.S.,
Atlantic City, N. J.

Many women between thirty-five and fifty years of age suffer from metrorrhagia and menorrhagia. Many are women who have borne a number of children or who have aborted one or more times. These patients suffer from no metabolic, poisonous, luetic, organic or infectious diseases, and a pelvic examination fails to reveal any distinct palpable lesion. After being subjected to repeated curettages, intermittent or continuous hemorrhage is still apt to continue.

The first attempt to place the etiology on a definite scientific basis was worked out by Scanzoni, who ascribed its cause to an atheromatous condition of the bloodvessels of the uterus. His contentions were subscribed to by Simonds, Cholmogroff, Solowij (24) and others, but it is my contention that the term arteriosclerosis cannot properly be applied to these cases.

In none of the cases were the patients suffering from any disease of the vital organs, nor did they show arteriosclerotic changes in the vessels of other parts of the body, not even in the pelvic vessels or the uterine artery. The pathological picture presented by the bloodvessels in the uteri removed differed materially from that seen in typical arteriosclerosis. In arteriosclerosis the morphological change commences in the intima and extends outward, while in these cases the growth of connective tissue was seen around the adventitia into which it finally extended. The media undergoes a muscular hypertrophy, probably compensatory, while the intima shows no deviation from the normal, with the single exception that occasionally there may be seen a slight increase in the epithelium. The bloodvessel lumina are kept wide open by the concentrically laid layers of connective tissue. In true arteriosclerosis there is a tendency toward the obliteration of the bloodvessel lumina by the growth of the intima. I venture to suggest that the term "hypermyotrophy," applied by Reinicke (3) is much more appropriate for the structural changes in the bloodvessels than arteriosclerosis.

In addition there is a great increase of connective tissue in the uterine walls between the muscle bundles, between the muscle fibres, and around the bloodvessels. As this increases there is a diminution of muscle structure from atrophy which shows here and there a hyaline degeneration. Much importance, says Novak (1) is attributed to the lack of elastic tissue and the hypertrophy of fibrous tissue in the muscle of the uterus. Pankow, quoted by Novak (1), describes the bloodvessel changes in the smaller vessels of the mesometrium as consisting of an increase in the elastic fibres of the vessels as well as the uterus itself. These changes were observed only in women who had borne children. Age played no part as they were found in quite young women.

ETIOLOGY.

The tendency among gynecologists in the past seems to have been to consider as arteriosclerosis, for want of a better name, all cases of uterine bleeding for which no other explanation could be found. It is obviously difficult and at times impossible to eliminate all possible causes of uterine hemorrhage. The question as to which of these findings, the bloodvessel changes or the connective tissue changes, is responsible for the persistent uterine hemorrhage in the preclimacteric period, seems to resolve itself into a hyperdevelopment of fibrous tissue in the uterine walls which takes the place of the exhausted and finally atrophied muscle fibres. With the diminution of muscle tissue and elastic fibres a loss of contractility occurs. This loss becomes greater after each succeeding pregnancy until uterine compensation is entirely broken. It is contended by Rabinovitz (29) and others, therefore, that the menorrhagia and metrorrhagia in these cases is due to an insufficiency and an inability of the uterine muscles to contract, and that it is not due to the friability or atheromatous condition of the bloodvessels. In other words, the bloodvessel changes are secondary to those taking place in the muscularis, as proved by the invasion of fibrous changes in the adventitia, by the compensatory hypertrophy of the media, and by the normal state of the intima. It is also contended that this condition is not the sequel of inflammatory reactions but is the result of biological changes.

Polak (2), on the other hand, considers this condition as practically always due to old infections of the uterus after repeated parturition or abortions with subinvolution and associated with metritis of a chronic type. The endometrium is a lymphoid structure without a submucosa. The prolongation of its tubular glands extends into the underlying muscular coat. In the course of time, says Polak, infective bacteria, in the form of serum, round cells, plasma cells, and leucocytes, are poured into the stroma and muscle structure. This thickens the wall of the uterus and increases its gross bulk. Muscle tissue is destroyed by pressure and its place is taken by fibrous tissue. The glands are larger and dilated. The arteries become thick walled and surrounded by a large amount of elastic tissue which inhibits normal muscular contractions from controlling the bloodvessels, hence bleeding is the most constant symptom, and Chalfant emphasizes the fact that the bloodvessels are increased in number and size.

Kelly is quoted as saying that it is a noteworthy fact that this disease is a local affection not associated with an arteriosclerosis of the other vessels of the body nor of the uterine artery itself. Arteriosclerosis cannot be considered as the essential and only cause of hemorrhage of this type. As a matter of fact, uteri in which a true atheroma of the vessels has been found have in a number of cases never had any pathological bleeding at all during the physiological life of the uterus. It is also possible that changes observed in the mucosa may be the result instead of the cause of the hemorrhage.

Fletcher Shaw (4), Seifert Saxinger, Olhausen and Finn all leaned toward the idea of subinvolution and chronic endometritis, but Hitschman and Adler disproved the occurrence of chronic endometritis except in rare instances. Fritsch, Cornil, and Pozzi all contributed articles and Theilhaber and Meier (5) elaborated the theory of "muscular insufficiency," asserting that any change in the endometrium was secondary to that of the myometrium. Quoting freely from Scott's (16) admirable review of the literature, Barbour (6), Hermann, Martin, and Rustner were all of the opinion that the main pathological change was one of arteriosclerosis, but Palmer Findlay (7) disagreed and went back to the idea of muscular insufficiency. Addinsell (8), Gardiner and Goodall (9) stated that any prolonged congestion caused hypertrophy or hyperplasia of muscular as well as connective tissue. If this is sufficiently prolonged the muscle fibres atrophy and the connective tissue predominates. Archibald Donald (10) opposed this idea believing that the changes in the endometrium were constant. Briggs and Hendry (11), after studying 104 cases, viewed the uncontrollable hemorrhage as a functional disturbance. Geist (12) and Novak also conclude that the bleeding is purely functional and that the causative factor is probably ovarian. Papers have also been contributed by Anspach (13), Von Lorenz (14), and Pantzer (15) suggesting that the menorrhagia may be purely functional.

HISTOLOGICAL FINDINGS.

From this summary of the literature it is obvious that the histological findings in cases of idiopathic uterine bleeding vary in the experiences of different observers and that there is no one constant finding. Most of the writers are agreed that a majority of the cases are of the subinvolution and chronic metritis type, with a thick walled and enlarged organ and with both the muscular and fibrous tissue increased. The bloodvessels are thick walled and there are large plaques of elastic tissue around many of them. But, says Scott (16), idiopathic bleeding also occurs from other types of uteri and it is not uncommon to find the small sclerotic uterus, or the large soft flabby one, bleeding just as profusely as the socalled fibrosis uteri. Moreover, it is possible to find many uteri exhibiting any or all of the described histological changes of vessels, musculature, and elastic tissue, and yet not be the seat of any abnormality in bleeding.

In the cases carefully studied by Scott (16) there were thirty-four which presented histologically all the earmarks of socalled fibrosis uteri, yet in which there occurred no pathological or abnormal bleeding. These uteri were removed in the course of operations for various pelvic conditions; eighteen were larger than usual, six were smaller than usual, ten were normal in size, and the microscopical findings varied as much as in the bleeding cases. The fibrous tissue was increased in twenty cases and normal in fourteen. The bloodvessels were thickened in twenty-four specimens, while in sixteen there was an abnormal amount of elastic tissue either in the wall of the vessel or just outside of it. The vessel walls were normal in eight cases, and yet all these thirty-four cases presented no abnormality of bleeding.

It is seen, therefore, that the histological findings of chronic metritis of fibrosis uteri are not present in all cases of idiopathic uterine hemorrhage, and in many cases where these changes are found and from our former reasoning patients who ought to bleed abnormally do not bleed at all. However, Scott (16) found that there was one histological finding constantly present and that was a glandular hyperplasia of the endometrium, the glands being greatly increased in size and number. He properly asks, "If there is no constant histological findings and the bleeding does not depend upon changes in the myometrium or the vessels, how is it to be accounted for?"

There are many things that seem to point to the fact that it is due to a disturbance of the endocrine equilibrium. It occurs only during menstrual life and always starts as a menorrhagia. It is particularly common to the periods of puberty and the menopause and it is at these periods that endocrine disturbances are most often abnormal. It often can be relieved by x rays or radium and the effect produced by these agents is primarily on the ovaries.

From a consideration of this rather exhaustive review of the literature on the subject, in which each writer has sought to prove his theory largely from the viewpoint of *post hoc, ergo propter hoc,* the idea is suggested to my mind that there are at least three different types of this condition. First, a large group, comprising probably the majority of cases which fall into the class of chronic metritis and consequent subinvolution. Second, the group of senile atrophy and contracted uterus, for it must be remembered that this type of idiopathic hemorrhage does occur after the menopause and these cases cannot be entirely ignored. It may also be true that atrophic changes may be taking place before the menopause is established. Third, a rather large class of cases that are distinctly of an endocrine type. These cases probably occur in women who in earlier years were accustomed to having free and prolonged flow as a normal habit, a great many of whom had never been pregnant or suffered from a miscarriage.

TREATMENT.

In a consideration of the treatment of this condition it is necessary to eliminate the presence of a submucous polyp, or a small intramural fibroid; the retained products of an old abortion, such as had been termed placental tumor; bleedings and congestions due to pelvic varicocele and cancer of the fundus. The differentiation between metritis and carcinoma is the most important and sometimes the most difficult problem that confronts the gynecologist. This question can be decided only by the aid of the curette and a microscopal examination of the scrapings by a competent pathologist. Indeed, hysterotomy may be necessary sometimes to determine just what condition exists inside the uterus. If the bleeding is of the idiopathic variety, curettement will control it temporarily, but usually after one or two periods the bleeding will begin again and often with increased severity.

X RAYS AND RADIUM.

Treatment may consist of x rays or radium, opotherapy with the endocrine glands, and if these fail, conservative surgery, which should be a supravaginal or panhysterectomy according to the indications. Radium and x rays would no doubt cure most of the cases and reduce the size of an enlarged uterus, but unfortunately not all of these cases are amenable to radium or x rays. If the pelvis has been the seat of previous inflammatory processes, such as peritonitis, salpingitis, or cellulitis, these agents are contraindicated.

ENDOCRINE TREATMENT.

Concerning endocrine treatment, Sehret (19) believed that hypothyroidism was responsible for many cases of excessive bleeding. The effect of mammary secretion upon the mechanism which causes menorrhagia or metrorrhagia has been suggested by Shober (17) and by Crouse. The whole question of the action of the endocrines is yet in such an experimental stage that it is quite impossible to make any dogmatic statements about them, but in my personal practice I have relieved many of these cases of metrorrhagia and menorrhagia by combinations of thyroid extract, posterior pituitary, mammary gland, and sometimes corpus luteum.

It is only fair to state, however, that where these glandular products have been effective has been in the cases in which there was little or nothing to denote chronic metritis or subinvolution, either in the history of the case or the examination.

Various writers have from time to time suggested one or more of these glands, but it is now well recognized that they accomplish little unless used in combination, because they work as a chain instead of individually. If the treatment by glandular extracts is carefully worked out in individual selected cases the results are sometimes brilliant, but on the other hand sometimes fail entirely. In the cases selected as purely functional this method is well worth a trial, because many of these women, especially the younger ones, will resent having their ovarian function completely stopped by radium or x rays, and if a result can be accomplished without resort to surgery it is much more acceptable to them.

HYSTERECTOMY.

Hysterectomy should be limited to those cases in which radium or x rays are not indicated, namely, in women whose pelves have been the seat of chronic inflammations with recurring exacerbations or other pelvic complications, and in the cases in which after a fair trial the endocrines have failed and the woman is drifting into chronic invalidism. If the cervix is scarred up with old tears, or there has been trauma to the lower uterine segment and the cervix is the seat of endocervicitis and in an unhealthy condition, then nothing short of a total hysterectomy is demanded.

The Clinical Value of Acidophilus Milk

By WILLIAM EARL CLARK, M.D.
and MATTHEW WHITE PERRY, M.D.,
Washington, D. C.

In January, 1922, at the suggestion of Dr. F. G. Cottrell, of the National Research Council, and with the permission of Dr. Leo F. Rettger, of the Department of Bacteriology of Yale University, we undertook an investigation of the possible clinical value of acidophilus milk in gastrointestinal disorders. We have now used the milk and observed its effect, with only slight interruptions, for eighteen months and are able to report observations on eighty-four adult patients. Each of these patients has taken a quart of milk each day for a period of six weeks.

When this study was started it had been clearly shown by Rettger and Cheplin and their coworkers, by well controlled experimentation, that by the use of preparations containing large number of Bacillus acidophilus the human intestinal flora could be markedly simplified, that it could be changed from a preponderatingly Gram negative to a preponderatingly Gram positive type, and that gas producing and putrefactive organisms could be almost completely stamped out or replaced by the Bacillus acidophilus. This had been shown by both animal and human experimentation and the results found were most striking. They had also shown that this transformation or simplification of the intestinal flora could be accomplished by the ingestion of large amounts of glucose and lactose, these sugars apparently furnishing the necessary pabulum for the growth of the Bacillus acidophilus normally present in small numbers in the human intestine. This work indicated, however, that in order to accomplish this result, large amounts of these sugars, between two hundred and four hundred grams, were required each day. They had also shown that the same change in flora might be accomplished by the ingestion of large amounts of whey broth cultures, or by a combination of the latter with the sugars mentioned above. A third way in which the same result could be accomplished was by the ingestion of milk cultures of the organism, either alone or better in combination with lactose in amounts usable clinically.

As already pointed out it had been shown that larger amounts of lactose than seemed practicable were required to cause a transformation of the intestinal flora. The majority of our patients were below their ideal weight. We found, furthermore, that the milk could be prepared without great expense and more reasonably than broth cultures could be obtained. Because of these reasons we thought it more practicable to use the acidophilus milk.

In all but twenty cases we have had the patients use with the daily quart of milk seventy-five grams of lactose. This has seemed a valuable addition, enabling the change in flora to occur much more rapidly and effectively and enhancing the clinical value of the preparation. The twenty cases in which the patients did not receive the lactose are included under the discussion of constipation. In the cases of all other conditions discussed the patients received lactose.

We have not attempted extensive laboratory studies on the stools of patients before and after the use of the milk. In the few cases in which we have satisfactorily done this our findings have coincided with those of Rettger and Cheplin. The transformation from a Gram negative flora to a preponderatingly Gram positive one has been striking, rarely, however, going higher than eighty per cent. of Gram positive organisms. Gas production, as tested by fermentation of one per cent. dextrose broth in the Smith tube, has generally been reduced.

Patients as a rule have not objected to the taste of the milk. It has a mildly acid flavor, less acid than Bulgarian bacillus milk, and is quite acceptable as a food. Most of the patients have stated that they liked it. All of the patients, with the exception of a group of six with chronic diarrhea, were on an ordinary well balanced diet. In the group with diarrhea roughage and bulk were eliminated, in so far as was possible.

Each patient was first put through a complete examination, consisting of history, physical examination, gastric analysis, examination of the urine, feces and blood, and blood Wassermann, blood pressure determination, gastrointestinal x ray study, and proctoscopic examination. Diseases other than those mentioned below were not present in these cases.

CONSTIPATION.

Fifty adult patients presenting themselves for the treatment of chronic constipation were given the milk over a period of six weeks. Each of these patients had had constipation for many years, the majority stating that they had been constipated all their lives. All were in the habit of taking some form of laxative routinely, the majority, thirty patients, every day in the form of a pill, saline or enema. Twenty patients were given the milk without lactose, and the remaining thirty were given the milk plus lactose as stated above (seventy-five grams per day). Thirteen of the latter group were patients who had been in attendance at the office for a year or more and in whom a satisfactory result had not been obtained.

The results in general show that acidophilus milk with lactose has a distinctly laxative quality. The milk alone in our series, however, did not show such an effect. Of the twenty patients who took the milk alone, eight reported a constipating effect, six a laxative effect, and six reported no effect in either way. Of the thirty patients given the milk and lactose, twenty-four reported a distinctly laxative effect, none reported a constipating effect, and only six reported no effect in either way. Of this group of thirty patients twenty-four were below their ideal weight, as calculated on the basis of age, height and sex. The general tendency was toward a gain in weight. Of the group using the milk and lactose, sixteen were able to discontinue all laxatives; the remainder found it necessary to use mineral oil or agar, preparations milder than they had hitherto used. With such symptoms as debility, lassitude and depression, commonly attributed to constipation or autointoxication, it is difficult to be definite. It has seemed to us, however, that there was marked improvement in such symptoms coincident with the correction of constipation by these means.

EXCESSIVE INTESTINAL GAS.

Patients who seemed to be especially benefitted were those who complained particularly of an excess of intestinal gas, of flatulence, and of the passage of large amounts of gas by rectum. We have observed twenty-seven such cases. A majority of these came under the constipation group, although we have included eight cases in which constipation was not present. Patients of this group complained of vague symptoms, of a sense of fullness, of heaviness, of shifting abdominal pain, socalled gas pain, and of explosive passage of gas. The neurasthenic habitus is especially evident in this group. Drowsiness, lethargy, a tired feeling or a feeling of being below par, are also symptoms commonly present in this group. Of the twenty-seven patients complaining of excessive intestinal gas, twenty-three reported marked improvement and four noted no effect. No patient in this series reported an increase of symptoms. In this group twenty-four out of the twenty-seven were on the average below weight, and again the general tendency was toward a gain. Those reporting a reduction in the intestinal gas also reported an improvement in the other symptoms mentioned.

ULCERATIVE COLITIS.

The use of the milk and lactose, as described above, in a case of ulcerated colitis of two years' duration, had no appreciable effect.

FUNCTIONAL INDIGESTION ASSOCIATED WITH CHRONIC MYOCARDIAL WEAKNESS.

Five patients, all elderly individuals between sixty and seventy years of age, in whom the findings were those of chronic myocardial weakness, presented themselves because of intestinal gas and bloating. At times the abdominal distention was so great as to seem to embarrass further the already greatly embarrassed circulation. Relief from the digestive disturbances in these cases was marked in all five. Mild constipation was relieved, and in one case with high indicanuria and marked lethargy almost approaching coma, but with a normal blood chemistry study, the use of the milk was coincident with a rapid clearing of the lethargy and of the indicanuria.

CHRONIC DIARRHEA.

Six cases of chronic diarrhea were studied, in all of which repeated examinations of the stools revealed no parasitic cause for diarrhea. In no case was there an achylia gastrica present and, as already stated, routine examination revealed no organic or constitutional disease other than catarrhal inflammatory changes in the rectal mucosa on proctoscopic examination. These cases were diagnosed as chronic enterocolitis. The longest case had stood six years, the most recent case one month. The average duration of the six cases was eighteen months. Rest in bed and a diet deficient in roughage was also employed. In all these cases the patients made a rapid recovery and have remained well at the end of one year. In an additional chronic case where achylia gastrica existed no benefit was experienced from the use of the milk and lactose.

SPRUE.

Our experience with sprue has been limited to one case since employing the acidophilus milk. The result, however, was so striking that it seems the case should be recorded. This patient, a resident of Havana, Cuba, had had for two years the classical symptoms of sprue. For one month a routine of rest in bed, with a diet free of roughage, and treatment consisting of opiates by mouth and of colonic irrigations of salt and witch hazel solution, availed nothing. The patient, in spite of consuming large amounts of food, continued to lose strength and weight and received no relief from the diarrhea. At this point she was put on the acidophilus milk and lactose and a striking change occurred. Coincident with the use of the milk and lactose there was rapid and complete recovery. At the end of one year she remains in normal health. She gained in weight from ninety-five to one hundred and sixteen pounds while under treatment and informs us by letter that she has continued to gain. At the beginning of the use of the milk small doses of opium were continued. At the end of four weeks this was discontinued. Irrigations which she had been receiving every other day were discontinued one week after starting the milk. There was complete relief of glossitis, explosive, watery, frothy movements; anemia of the secondary type; emaciation and weakness.

In our opinion the acidophilus milk was responsible for the good result in this case of sprue and we feel that it is a form of treatment which could well be investigated by those handling large numbers of cases. Repeated routine examinations for ova and parasites were negative. Gram smears of the feces before use of the milk showed the following: Gram positive bacilli, twenty-one per cent.; gram negative bacilli, thirty-seven per cent.; gram positive cocci, twenty per cent.; gram negative cocci, twenty-two per cent.; gram positive organisms, forty-one per cent.; gram negative organisms, fifty-nine per cent. Six weeks after starting the milk and lactose the following was found: Gram positive bacilli, seventy-one per cent.; gram negative bacilli, nineteen per cent.; gram positive cocci, four per cent.; gram negative cocci, six per cent.; gram positive organisms, seventy-five per cent.; gram negative organisms, twenty-five per cent.

CHRONIC ECZEMA.

Four cases of chronic eczema were referred by dermatologists. These cases had not yielded to usual treatment and it was the feeling of the specialists who referred these cases that some form of toxic intestinal absorption might be at the basis of the eczema. Coincident with the use of the milk and lactose three patients recovered and one did not improve.

PSYCHONEUROSES.

In eight cases diagnosed as psychoaneuroses, the patients were given the milk and lactose in the routine way. All of these patients had been the rounds of medical men and were under the impression that their symptoms of depression and nervousness were due to autointoxication. Shifting abdominal pain, gas pain, irregular passage of mucus by bowel, nervous instability, more or less insomnia, introspection, were outstanding features in this group. In these cases four patients reported improvement and four reported no improvement.

At the end of six weeks' treatment all patients were advised to continue the use of the lactose and to date the majority have continued to do so. Our experience is that the continuation of this sugar maintains the new flora and the beneficial results obtained. On stopping the lactose there is a rapid reversal to the original type of flora.

For the preparation of the milk in the beginning of the work we are greatly indebted to the officials of the Hygienic Laboratory of the United States Public Health Service. During January, February, and March of 1922, this laboratory prepared the milk and cooperated in every possible way in the clinical investigation. Dr. George W. McCoy and Mr. Conrad Kinyoun, of the laboratory, report the following method of preparation: "Approximately nine hundred and fifty cubic centimetres of skimmed milk were placed in clean quart bottles, plugged with cotton and autoclaved for twenty to thirty minutes at fifteen pounds' pressure. Parenthetically, it is believed that twenty minutes is ample, and that much of the caramellizing of the lactose can be avoided by the shorter sterilization. The bottles were then cooled to 40° to 50° C. and inoculated with ten cubic centimetres of twenty-four hour acidophilus culture, the cotton plug replaced by an ordinary milk cap and incubated. At the end of sixteen hours the product was usually well coagulated, was transferred to 15° C., and kept in storage up to six days."

At this point the production was taken over by the Chestnut Farm Dairies, of Washington, D. C., and produced by the same method and without cost to the patients. To Mr. Henry M. Brauner, of this concern, we are greatly indebted. It has indeed been refreshing to see the management of a commercial concern cooperate wholeheartedly in a medical investigation. After two months' production the work was taken over by a local biological laboratory which has commercialized the product and has worked out the following scheme of production, the milk produced in this way being highly satisfactory: Quart bottles filled with fresh, unpasteurized skimmed milk are steamed at 100° C. for an hour on each of three successive days. After the milk has cooled below 37° C. it is inoculated with five to twenty c. c. of a culture. The amount of the inoculum depends on the speed of the organism. If the inoculum is fresh from the incubator the minimum amount is used. If it has been in the refrigerator for ten days or more the maximum amount is needed. The inoculated milk is then incubated for twenty-four hours at a temperature of 37° C. A lower temperature, requiring a longer period of incubation, produces a milk that is too acid, while the optimum temperature of 42° to 44° C., although it cuts down the time of incubation, makes a coarser product which is generally covered with whey. The method described produces a culture of fine flavor and texture without a trace of whey, unless the bottles are disturbed during the process of incubation. The milk is chilled for a day before it is delivered.

Further Observations on the Therapeutic Effect of Bacillus Acidophilus Milk

By HARRY A. CHEPLIN, Ph.D.,
Syracuse, N. Y.,
Assistant Professor of Bacteriology, Syracuse University.

INTRODUCTION

Since the announcement of the classical researches by Escherich, the discoverer of the Bacillus coli, the bacteriology of the intestinal tract has been a subject of a great deal of investigation. However, success in these endeavors has been limited, with few exceptions, chiefly to the discovery and systematic study of microorganisms which are manifestly disease producing and which exert their noxious influence upon the host within relatively short periods of time, as for example, the etiological agents of cholera, dysentery, typhoid and paratyphoid fevers. The more subtle microbic processes which are incessantly carried on in the alimentary canal, the various types of intestinal bacteria, their relations to each other and to the welfare of the host, their relative numbers, the laws which govern their metabolic activities and underlie their presence and physiological significance in the digestive tract, the ways and means which regulate the preponderance of one type of bacteria over another, represent researches into phases of intestinal microbiology which are, as yet, comparatively new, and the extremely vital importance of which is attested by the universal interest and concern which are manifested in them by the bacteriologist and medical man alike.

While it is, of course, true that the intestinal flora, ever harbored in the recesses of the bowel, is by no means constant ordinarily and, especially in case of disease, resulting from a direct invasion of pathogens, we are, nevertheless, now fully aware of the fact that under conditions of normal functioning within the alimentary canal, the intestinal flora is fundamentally a physiological unit rather than a heterogeneous collection of adventitious microbes and bears a definite relation to the diet of the host. In fact, under normal physiological conditions, the fundamental factor controlling the types of bacteria developing in the intestinal tract is the chemical composition of the food ingested. That is to say, as the chemical character of the diet is changed those types of bacteria which are unable to accommodate

themselves to the new nutritive environment tend to decrease in numbers, while more adaptable organisms take their place. The well established fact that diet exercises a most profound influence in determining the predominance of one or another type of bacteria vegetating within the enteric tract, led to investigations relative to the question of transforming and simplifying the ordinary mixed intestinal flora through diet in conjunction with the oral administration of properly qualified organisms or by the latter process alone.

The work of Metchnikoff is too well known to justify any elaborate account of it in this paper. Realizing the presence in the alimentary canal of extremely large numbers of bacteria, the influence which the unrestrained activity of these organisms might conceivably exercise upon the general health of the host, and appreciating, moreover, the failure to annihilate them through sterile diet, colonic irrigations, starvation and chemical antiseptics, Metchnikoff proposed to combat the pernicious toxicogenic bacteria by infecting the intestinal tract with lactic acid bacilli, namely, Bacillus bulgaricus. Metchnikoff's proposal to fight these intestinal proteolytic bacteria on their own battlefield by the introduction of an antagonistic microbic army, gave birth to an entirely new and interesting field of study, namely, bacterial implantation within the intestinal tract for therapeutic purposes. The view that the ingestion of Bacillus bulgaricus brings about a displacement of the harmful intestinal microbes, thus leading to an improved physical condition, gained a firm hold in the minds of physicians, scientists and laymen alike.

Repeated attempts by Cheplin and Rettger in their recent extensive investigation to establish Bacillus bulgaricus in the alimentary canal of albino rats and of man through the administration *per os* of extremely large numbers of this organism were entirely unsuccessful. At no time during the course of experimentation was Bacillus bulgaricus recovered from the feces of man or the white rats or from any portion of the digestive tract of the rats, irrespective of whether the organism was fed alone or with a utilizable carbohydrate, such as lactose. Cheplin and Rettger pointed out, however, that bacterial implantation within the digestive tube was possible and could be accomplished only when properly qualified organisms were used. The bacterium selected for this purpose was Bacillus acidophilus. They demonstrated that transformation of the fecal flora, resulting in complete implantation of Bacillus acidophilus may be brought about easily by the oral administration of proper amounts of, 1, lactose or dextrin; 2, viable whey broth or milk cultures of Bacillus acidophilus, or 3, a combination of lactose or dextrin and the acidophilus cultures, in which case the amounts of each were cut in half. The claim is made that Bacillus acidophilus is a normal inhabitant of the large intestine of both animals and man and constitutes a logical candidate for simplifying the fecal flora for therapeutic purposes, while Bacillus bulgaricus, on the other hand, is not, so far as is known or could be ascertained, of intestinal origin and will under no circumstances accommodate itself to the intestinal environment.

The belief that a change from the ordinary, mixed, proteolytic fecal flora to one strongly dominated by Bacillus acidophilus is both possible and desirable, afforded a new avenue of approach to this complex subject. Viewed from this angle, the question naturally arose as regards the extent of the possible therapeutic merits attached to an acidophilus predominating fecal flora. The observations of Cheplin and Rettger have shown that Bacillus acidophilus accomplishes the results that Metchnikoff ascribed to Bacillus bulgaricus. These claims were since confirmed by Cheplin and Wiseman, Kopeloff and Cheney, and Gompertz and Vorhaus, who reported satisfactory treatment of chronic constipation and diarrhea with milk cultures of Bacillus acidophilus reenforced with lactose.

Cheplin, Fulmer and Barney, in their studies on the effect of Bacillus acidolphilus milk in a series of cases of chronic constipation, diarrheas and mucous colitis, found that the milk culture, when taken in sufficient amounts, exerted a beneficial influence clinically by removing the toxic symptoms and regulating the fecal eliminations from the bowel.

In view of the encouraging results which I have obtained in my earlier experience in connection with the therapeutic effects of Bacillus acidophilus milk, it was deemed highly desirable to extend the observations on a larger group of clinical cases. The chief object in conducting the feeding experiments presented in this paper was to implant Bacillus acidophilus within the alimentary canal of man and, while

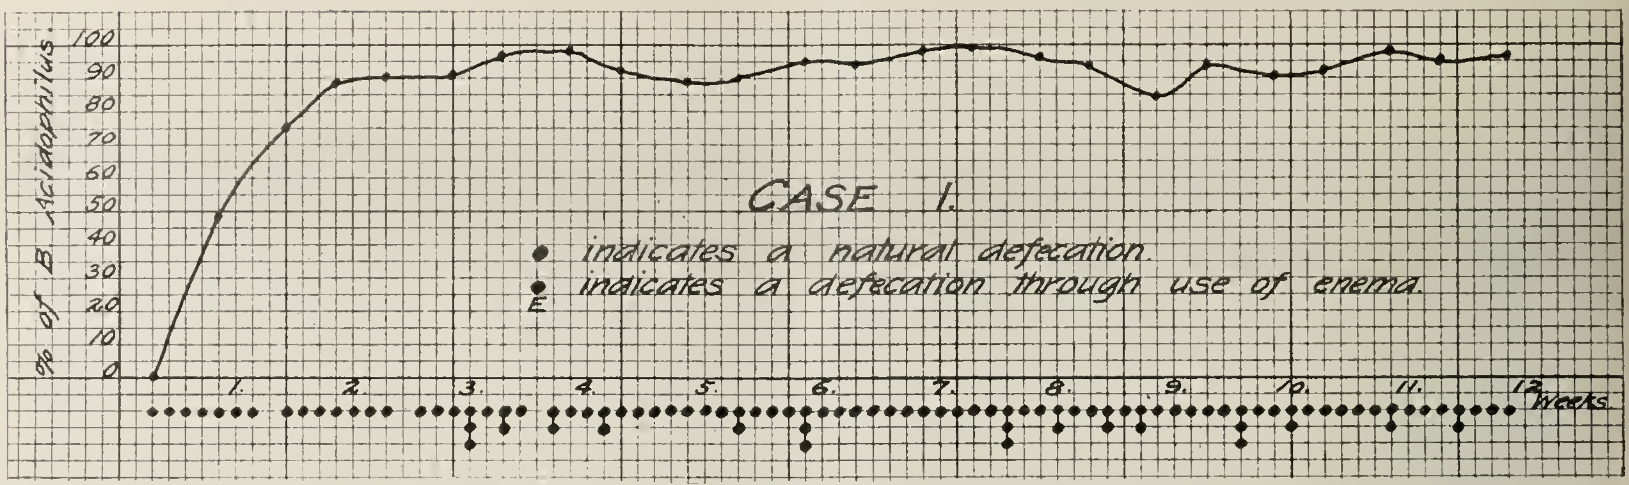

Chart. 1.—Case I. Constipation.

maintaining it as the dominant intestinal organism, to determine what improvements, if any, were manifested clinically. In other words, my aim was to establish, if possible, a correlation between a simplified aciduric flora represented strongly by Bacillus acidophilus and any changes which may be noted in the clinical picture.

In studying the therapeutic effects of the oral administration of Bacillus acidophilus milk, either alone or in combination with different amounts of lactose, no difficulty was experienced in enlisting the friendly cooperation and advice of practising physicians, who not only supplied me with many of the most interesting and severest cases, but who also furnished clinical histories of the individual cases and in several instances with x ray photographs. The subjects under discussion may be conveniently subdivided into the following two groups: 1, chronic constipation with the symptoms of socalled autointoxication and other accompanying disturbances, eleven cases; 2, chronic diarrhea and mucous colitis, three cases. These fourteen cases are exclusive of those which have come under my observation within the past six months. A full account of those results will be published at an early date. Particular attention is called to the fact that no patient was accepted for treatment except through advice by a practising physician.

METHODS

The subjects were requested to bring to the laboratory at least one specimen of stool before they were eligible for the acidophilus treatment. In all of the accompanying curves and Table I the first evacuation represents the stool furnished prior to commencing the acidophilus milk treatment. After the initial administration of the milk culture, with or without stated amounts of lactose, the patients were instructed to supply the laboratory with at least two specimens of stool each week. At no time during the investigation were any provisions or strict regulations made as to diet, except that the subjects were urged to refrain from the use of any food which by personal experience or training they knew to be likely to prove injurious. The milk culture and lactose, the amounts specified in Table I, were ingested in three equal doses, morning, afternoon and evening, two to three hours after meals, in addition to the ordinary daily dietary régime. The powdered lactose was added to the milk culture after the incubation period and the contents thoroughly shaken. It was definitely arranged with the subjects that no cathartics or laxatives be taken throughout the entire experimental period. In the event of no response during forty-eight consecutive hours, enemata consisting of two to three parts of water and one part of the milk culture were resorted to. In the diarrheal cases the treatment consisted in the daily oral administration of one thousand c.c. of the acidophilus milk without any added lactose, owing to the fact that this sugar, when taken internally in sufficient amount, exerts a marked laxative effect. Whenever the stimulation of peristalsis became too marked the volume of the culture taken daily was reduced to five hundred c.c. (Table I).

BACILLUS ACIDOPHILUS MILK

In view of the extreme importance attached to the use of Bacillus acidophilus milk the following brief description of the method of preparation and of its known properties is given.

Fresh skimmed milk is sterilized by autoclaving

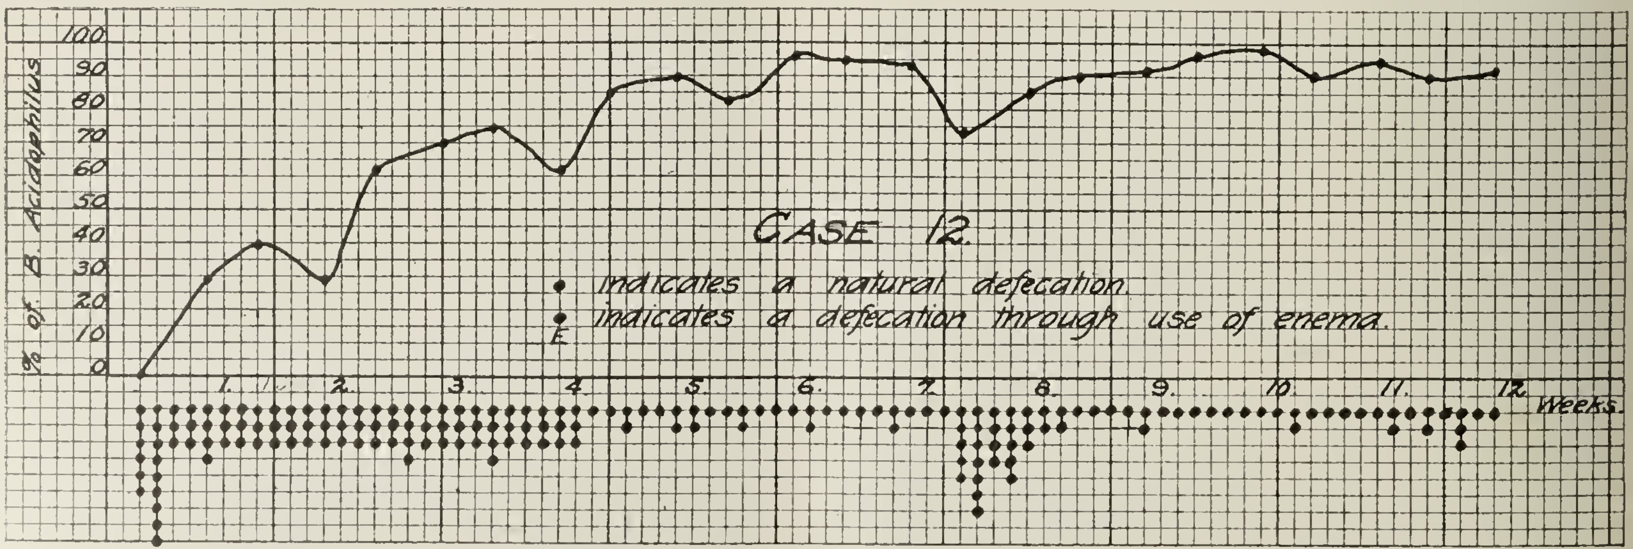

Chart 2.—Case II. Mucous colitis.

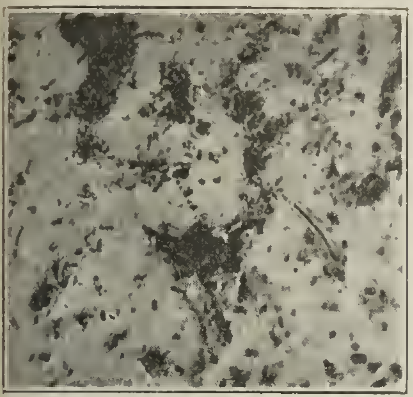

FIG. 1.—Gram stained film from fecal suspension before the administration of acidophilus treatment. Note complexity of intestinal flora. X 1000 diameters.

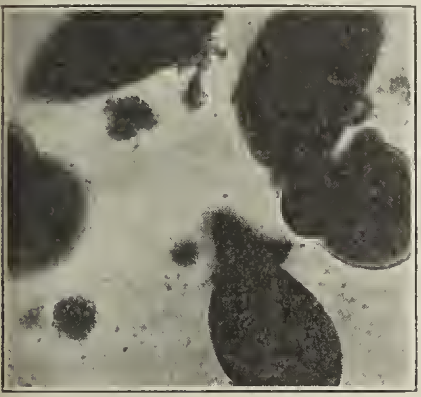

FIG. 2.—Two day old colonies on whey agar plate at 37°C. from fecal specimen two days after commencing treatment. Note small number of Bacillus acidophilus colonies, coarsely granular, fluffy, with very indeterminate wisp-like margins. X 40 diameters.

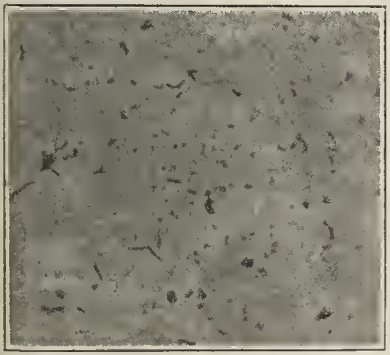

FIG. 3.—Gram stained film from fecal suspension four days after beginning acidophilus treatment. Note the simplified character of the bacterial flora dominated by acidophiluslike rods. X 1000 diameters.

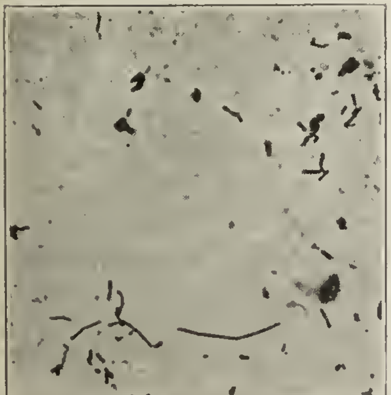

FIG. 5.—Gram stained film from fecal suspension eight days after beginning the acidophilus treatment. Note complete transformation of the intestinal flora. X 1000 diameters.

at an extra pressure of fifteen pounds for twenty to twenty-five minutes or longer when more than one thousand c.c are sterilized in a given container. For this purpose pyrex Erlenmyer flasks (fifteen hundred c.c. capacity) have been employed in the present investigation and were found to give admirable service. Properly heated milk should have a light yellowish cream color and not be distinctly browned. After cooling to at least 37°C. the milk is inoculated with a pure culture, preferably mixed strains, of Bacillus acidophilus and incubated at 35-37°C. for twenty-four to thirty-six hours. In this work six strains of Bacillus acidophilus were employed as the inoculum and at least ten c.c. of such inoculum are transferred for each litre of milk so treated. After the completion of the full incubation period, the milk coagulates and the casein appears as one solid block of curd, extremely soft in consistency, with a thin layer of clear whey over the surface. Upon thorough shaking the curd disintegrates into a finely subdivided state and the milk acquires a very smooth consistency which resembles that of rich cream. The acidity of Bacillus acidophilus milk is never high, as compared with that of ordinary Streptococcus lacticus or Bacillus bulgaricus milk, seldom reaching more than one per cent. The pure acidophilus milk possesses a decidedly characteristic odor and taste and should be agreeable to persons who do not ordinarily have a dislike for high grade buttermilks. The milk culture should be cooled after incubation, either in a cool room or refrigerator, clean and free from undesirable odors which may be absorbed, in order to enhance materially the palatability of the product. If it is found necessary to reenforce the acidophilus milk with lactose to insure maximum therapeutic effect in the shortest period of time, as is the case with individuals suffering from chronic constipation, the sugar may be added at the time the culture is taken. It will be expedient to agitate thoroughly the lactose and the milk culture and allow the mixture to remain for two hours or more in a cool place. This will permit a portion at least of the sugar to dissolve and thus reduce the gritty character of the lactose enriched milk.

The acidophilus milk is tolerated by most persons, even by those who are unable to retain the simplest diets prescribed for convalescents. In my experience with the acidophilus milk during the past three years, there were encountered individuals who could not tolerate sweet milk, raw or pasteurized, in any form, but who consumed acidophilus milk in quart lots daily for several months with complete impunity.

Upon ingesting one thousand c.c. of lactose enriched acidophilus milk, most of the patients complain during the initial four to ten days of a feeling of fulness, bloating or distention of the abdomen and abnormal flatulence. These undesirable symptoms, causing at times considerable annoyance to the patient, cannot, unfortunately, be avoided. The cause of these symptoms is quite apparent. The ingested lactose, by virtue of its incomplete absorption, when taken in amounts of one hundred grams or more, passes on beyond the ileocecal valve and into the colon, and is there vigorously attacked by the large gas producing bacterial army, particularly Bacillus coli and Bacillus welchii, with the evolution of enormous quantities of gas. As the transformation

FIG. 4.—Forty-eight hour colonies on whey agar plate at 37°C. from fecal suspension four days after initial ungestion of Bacillus acidophilus. Note the transformation effected under such dietary conditions and the dominance of acidophilus colonies. X 40 diameters.

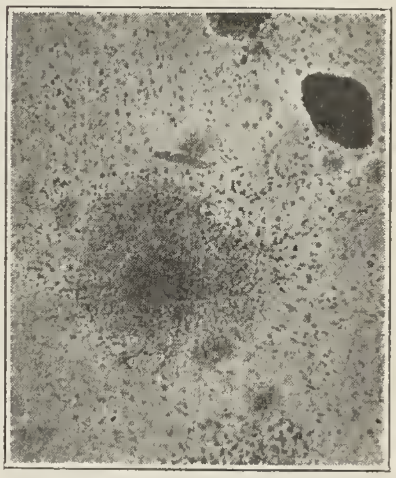

FIG. 6.—Two day old colonies on whey agar plate at 37°C. from fecal specimen eight days after the initial administration of the acidophilus culture. Note the marked transformation of the fecal flora and the predominance of Bacillus acidophilus colonies. X 75 diameters.

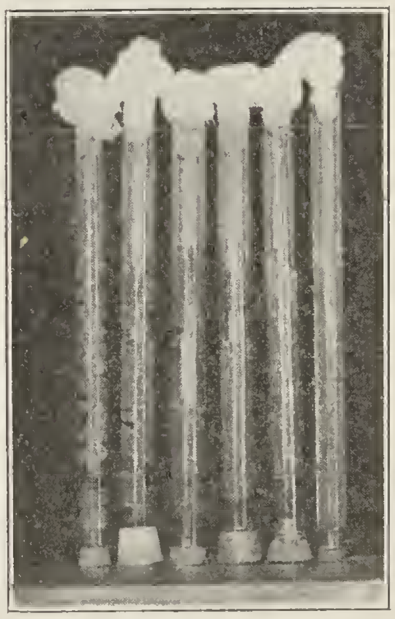

FIG. 7.—Veillon tubes. These tubes were used in my qualitative estimations of the relative amounts of gas produced by the fecal microbes. Note the gradual diminution of gas production, from left to right, as the intestinal flora approaches the mark of maximum transformation from the ordinary complex type to one in which the dominating organism is Bacillus acidophilus.

of the fecal flora progresses, with the concomitant diminution of the gas producing microbes, the aforementioned symptoms and distress gradually disappear. As long as Bacillus acidophilus, which is absolutely devoid of any gas producing properties, holds sway within the digestive tube, the amount of intestinal gases is highly minimized.

BACTERIOLOGICAL EXAMINATION OF STOOLS.

In all of the experiments recorded here the change in the bacterial picture of the intestinal flora and the implantation of Bacillus acidophilus were carefully determined by bacteriological examinations of the stools twice each week. The method employed was essentially the one advanced by Cheplin and Rettger and was briefly as follows: 1, Plating of fecal suspensions in saline on whey agar or dextrose agar (when the former was not available) and the numerical relationship of Bacillus acidophilus colonies to all other types expressed in terms of percentage. 2. Preparation of deep Veillon tubes for detection of gas producing organisms of both aerobic and anaerobic types. 3. Staining by the Gram method of fecal smears made on ordinary slides for a direct microscopic count and differential study of bacterial types. These methods, while short and simple in execution, proved to be most valuable and indispensable in this investigation, especially in the attempts made to correlate the bacteriological changes and the clinical findings. The accompanying curves and table demonstrate the relation between Bacillus acidophilus implantation and its tendency to regulate daily defecations.

EXPERIMENTAL BESULTS.

Throughout the entire series of experiments fourteen clinical cases were employed. The entire work involved the preparation of 1,100 litres of Bacillus acidophilus milk and the bacteriological examination of 310 stools. Brief clinical histories of all cases are given below together with treatment and results.

CHRONIC CONSTIPATION.

Case I.—The patient, white, female, engaged in stenographic and secretarial work, presented a history of most obstinate constipation for at least eight years, complaining of fullness of the abdomen, of gas and pain in the epigastric region, of an almost constant headache, general discomfort after meals accompanied by a peculiar feeling of malaise and dizziness, of visual disturbance, loss of energy and initiative, melancholia and other indications of considerable lessened mentality. It was absolutely necessary for her to resort regularly to unusually large doses of various cathartics and laxatives as well as colonic irrigations in order to induce bowel evacuations. She stated that for the past fourteen months the use of drugs and enemas yielded only partial relief of very short duration.

Treatment consisted of daily oral administration of one thousand c. c. of Bacillus acidophilus milk to which one hundred grams of lactose were added. Patient was under treatment for twelve weeks.

Result.—Subject responded immediately, reporting a normal bowel movement after the first litre of the milk culture was ingested and continued to report at least one daily evacuation, barring three exceptions, for the remainder of the experimental period. During this period the subject also reported two stools a day on ten different occasions and three defecations on four other separate days. There was an apparent change within the first two weeks in the patient's general condition and by the end of the tenth week said she had complete relief from gaseous distention and pain and discomfort in the epigastric region. Her headaches and mental and visual disturbances disappeared and she resumed her daily duties with, as she repeatedly stated in person, new strength and endurance. There was an increase of eight pounds in body weight and the patient reported a continuance of satisfactory bowel movements three weeks after the discontinuance of the Bacillus acidophilus milk.

By referring to the graph it will be clearly seen that within twelve days the fecal flora was markedly transformed, strongly dominated by Bacillus acidophilus. Attention is called particularly to the correlation which exists in this case between the simplification of the intestinal flora and the first noticeable improvement in the clinical picture.

CHRONIC DIARRHEA AND MUCOUS COLITIS.

Case II.—The patient, a white female, had been engaged in relief work in the Near East for three years. While there she was seized in 1919 with an attack of acute diarrhea accompanied by tenesmus. The stools contained considerable mucus and at times were quite bloody. After recovery she returned to the States in 1920. During the following year she experienced two recurrences of most violent diarrheal attacks accompanied by large amounts of mucus. It was not at all uncommon to record as many as eighteen movements a day. She was emaciated and subject to acute pain in the descending colon. The bacteriological examinations were negative for Bacillus dysenteriæ. She was sent to my laboratory following an attack of profuse diarrhea and the first stool presented was watery, of pronounced putrefactive odor, of greenish dark color and contained considerable mucus. The bacterial flora consisted chiefly of Bacillus coli and many other slender gram negative dysenterylike rods. Bacillus welchii and enterococci were also in abundance.

Treatment consisted of one litre of plain Bacillus acidophilus milk administered daily. The patient was under observation twelve weeks.

Result.—On the day previous to commencing the treatment the subject reported six movements and twenty-four hours following the initial ingestion of the litre of the milk culture the condition was somewhat aggravated, the patient asserting that she voided nine specimens with increased amounts of mucus and some blood. By the third day the number of stools decreased to three, appearing lighter in color and less watery. She continued to void three and occasionally four specimens a day for the next three weeks. By the end of the fourth week the abdominal pain and distress had practically disappeared, the diarrheal condition and mucus had almost completely ceased, and the stool became normal and formed. She continued apparently normal for three weeks reporting one or two defecations a day without blood or mucus, although in a few stools mucus could be demonstrated microscopically. Beginning with the eighth week there was a slight return of the diarrheal conidtion, not attended, however, by any blood or mucus. The subject confessed that on the night before the partial recurrence she indulged freely in various foods including excessive portions of meat, pastries and sweets. This setback lasted four days and a return to formed stools was evidenced for the remainder of the course of the feeding experiment. Except for the aforementioned recurrence she was, according to all appearances and information, and her own claims, in normal health for the rest of the experiment. The transformation of the fecal flora was complete after the fifth week. There was an increase in weight of ten pounds. The subject has on two occasions, six weeks after discontinuance of treatment, informed me that she has suffered no serious recurrence.

EVALUATION OF THE BACILLUS ACIDOPHILUS THERAPY.

From the general observations throughout this investigation I feel confident of the therapeutic value of Bacillus acidophilus in the treatment of the intestinal conditions set forth in this paper. That it readily lends itself to complete implantation within the human alimentary canal to the exclusion of almost all other types of intestinal microbes is now a well established fact. Its successful acclimatization and colonization in the large intestine, where the bacterial cesspool is most active, is of extreme importance both from prophylactic and therapeutic points of view. The acidophilus milk, by virtue of the large number of viable organisms which it contains, exerts a marked beneficial influence upon constipation by regulating the fecal eliminations from the bowel, while in the diarrheas and in mucous colitis its effects are manifested by a gradual restoration of formed stools and the elimination of mucous discharges. Simultaneous with these regulatory phenomena important changes are noted clinically. There appears a pronounced relief from the toxic symptoms which previously existed. This bears a definite and consistent relationship to the simplification of the intestinal flora. In my entire experience I have not, as yet, observed a single individual manifesting even a tendency toward constipation while harboring an acidophilus dominating flora.

Bacillus acidophilus is not a toxicogenic organism. No toxic or other harmful substances are ever elaborated from its metabolic activities. It is now well known that Bacillus acidophilus is present in large numbers in the digestive tract of normal nurslings, whose resistance to intestinal toxemia is at the lowest possible ebb, and it would appear, therefore, that its chief function is to confer protection upon the young against the invasion of numerous putrefactive toxin elaborating bacterial types found in adults. The virtue of Bacillus acidophilus, as a remedial agent, lies not only in its ability to suppress Bacillus coli, as affirmed by Gompertz and Vorhaus, but also to a very large extent to its inhibiting effect upon Bacillus welchii, Bacillus proteus, Bacillus putrificus and various other undesirable toxicogenic intestinal microbes.

In view of the conclusive evidence obtained from the numerous experiments which I have thus far conducted, it appears that viable acidophilus milk cultures of proper concentration, when taken *per os* in sufficient quantities and under optimum conditions, merit their therapeutic application in the treatment of chronic constipation, diarrheas and all their attendant symptoms. It would also seem logical to assume that Bacillus acidophilus milk should prove beneficial, not only in the treatment of pathological conditions which are directly or indirectly referable to a disturbed function of the main mechanism of elimination, but also in specific intestinal infections, as, for example, typhoid, paratyphoid, Bacillus enteritidis (Gaertner), cholera, and dysentery. Torrey has demonstrated in his studies with typhoid patients that the ingestion of two hundred and fifty to three hundred grams of lactose a day in addition to the other elements of the Coleman-Shaffer diet, which effected a marked proliferation of Bacillus acidophilus, conserved body weight, modified the course of the disease, and reduced the mortality.

The profound influence which Bacillus acidophilus exerts upon the activities of intestinal bacteria, in so far as it is now known, would, indeed, warrant the assumption that a new chapter in the annals of therapeutics has been opened. The results of this investigation are apparently favorable for a new avenue of approach to this type of bacteriotherapy. However, to sound a word of warning and caution at this time should not be amiss. We need but recall the socalled epoch making work of Elie Metchnikoff on the prolongation of human life through the removal of the injurious putrefying intestinal microorganisms by ingesting cultures of Bacillus bulgaricus. His advocacy of the use of Bacillus bulgaricus, "the longevity bug," has spread to every corner of the earth. In fact, so general has the use of the Bacillus bulgaricus cultures become that the market is actually flooded with various commercial preparations, in the form of powders, bouillons and tablets.

The claims of Metchnikoff and his colleagues were not confirmed, however, by many investigators who have shown conclusively that Bacillus bulgaricus does not acclimatize itself in the large intestine, where the microbic army is at its highest point of concentration and metabolic activities. It should be borne in mind that in the experiments conducted by Metchnikoff and his followers large quantities of milk soured with Bacillus bulgaricus were consumed and hence the conditions for the development of Bacillus acidophilus were most favorable, as has been clearly set forth by Cheplin and Rettger in various publications. Since Bacillus acidophilus, the normal inhabitant of the lower levels of the intestinal tract of man, closely resembles and is practically indistinguishable from Bacillus bulgaricus morphologically and even culturally to a very large extent, it is not illogical to assume that the former has undoubtedly been mistaken for the latter. This assumption is highly strengthened by referring to the observations made by Belonowsky, an associate of Metchnikoff, who noted that the intestinal flora of young nursing mice was of the same character as in older mice which received the Bacillus bulgaricus milk cultures. I examined the feces of nursing mice on several occasions and found large numbers of Bacillus acidophilus.

It would seem expedient, in view of the past history of bacteriotherapy and particularly the fate of Bacillus bulgaricus, to call attention to the fact that the Bacillus acidophilus therapy does not represent a cure for all diseases to which man is heir. Moreover, no claim is made that all cases of pathological disturbances falling within the category outlined above will necessarily respond to the acidophilus treatment. In many cases it may require considerable time, anywhere from two to six weeks, before any improvement is noted clinically.

VALUE OF TREATMENT.

The acidophilus treatment is not a panacea, nor an elixir of life. The administration of small amounts of cultures of Bacillus acidophilus in tablespoonful or tablet doses, unless extremely concentrated by special processes, should not be expected to effect transformation of the fecal flora and yield beneficial results.

Bass has shown the impracticability of commercial tablets and capsules. He estimates that it requires twenty tons of tablets or capsules to contain as many viable bacteria as are present in one litre of the Bacillus acidophilus milk culture. More recently, Cheplin, Post and Wiseman examined a large number of commercial tablets and their bacteriological findings fully confirm those of Bass.

The proper execution of this method of treatment involves the daily ingestion, for varying periods of time, of at least fifty billions of viable acidophilus bacilli. It is for this reason that I strongly urge the use of the acidophilus milk culture, in amounts to be governed by the response of the individual cases. This definitely established quantitative relationship between the number of living bacterial cells ingested and the bodily improvement which one wishes to attain should ever be kept in mind in order to insure the fullest benefits from the Bacillus acidophilus therapy and preclude its falling into ill repute.

The author's references will appear in his reprints.

Hematosalpinx Associated with Ruptured Tubal Gestation

By LAMBERT ROGERS, M.R.C.S. Eng.,
London.
Late House Surgeon, The Middlesex Hospital.

Rubinovitz and others have drawn attention to the fact that tubal gestation is not infrequently associated with disease of the opposite Fallopian tube which may be the seat of hydrosalpinx, pyosalpinx, or hematosalpinx. This is illustrated in the following case which also affords another instance of the curious circumstances in which rupture of a gravid tube may occur.

Case.—A widow, aged twenty-nine, was seized with abdominal pain when in a music hall on Tuesday evening, September 20, 1921. She was obliged to leave on account of her distress, was brought to hospital in a taxicab, and admitted into one of Mr. Webb-Johnson's beds. It was ascertained that she had been operated upon for appendicitis in November, 1917, and for renal calculus in September, 1918. She was a thin woman with a careworn expression giving her an appearance of being prematurely aged. The lower abdomen was tender on palpation and she had slight vaginal bleeding.

There was a history of two miscarriages, one at three and a half, the other at six and a half months, but she was the mother of two healthy children, and had been a widow since May 30th. Menstruation had been regular until July. On the 16th of that month she commenced to menstruate normally, but missed the whole of August and began again on September 2d. Since that date there had been bleeding up to the time of admission. Pain in the lower abdomen, most acute in the left iliac fossa, was first noticed on the Saturday before admission. On Sunday she vomited and had a transient attack of pain. On Monday she felt better and was free from pain, which, however, returned on the Tuesday evening when she was in the music hall as related.

Suspecting leakage from a gravid fallopian tube I kept her under observation. The morning following admission into hospital she felt so much better that she asked permission to go to her home, but was advised to remain until the next day. At 5:30 p. m., it was obvious that she was suffering from profuse internal hemorrhage. I opened the abdomen in the midline and on incising the peritoneum blood rushed through the opening. Introducing my hand into the pelvis I seized the left tube from which blood was spurting while my assistant completed the peritoneal incision. Then clamping the tube, we removed the greater part of it, leaving the ovary. The right tube was distended, as well as the left, and contained blood clot, and my colleague, who was assisting me, remarked that surely it was gravid also. We removed the right tube and ovary. The appendix was healthy and pelvic in position, despite the appendicectomy of 1917.

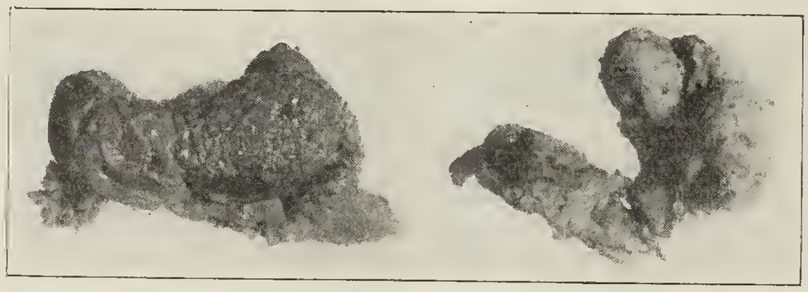

FIG. 1.—The two fallopian tubes seen from behind. The left is gravid, the right shows old salpingitis and contains blood clot.

After removing the clot and fresh blood from the colonic cavity, the abdomen was closed without drainage. Primary union occurred; the patient made an uneventful recovery, and left the hospital convalescent on the fourteenth day after the operation.

The illustration shows the two tubes from behind, the left contained chorionic villi, but I could not demonstrate these in the right which showed old salpingitis and contained blood clot.

I am indebted to Mr. A. E. Webb-Johnson for permission to record this case.

A Case of Bilateral Thromboangiitis Obliterans*

By M. J. STONE, M.D.,
New York.

This case herein reported is considered of interest because of the development of arterial changes in one limb while under observation and treatment with apparent clinical improvement in the other limb. Also because it contrasts the effect of amyl nitrite inhalation on a bloodvessel recently involved against one in which adventitious and perivascular fibrotic changes had occurred.

CASE.—The patient, Mr. A. W., forty-one years of age, white, Lutheran, was a native of Esthonia (Finland), a sailor until ten years ago, and painter since then. His family history is not known. He was admitted to the medical service of Lebanon Hospital on March 15, 1922, complaining of severe pain in the small toe of his left foot. This was gradual in onset, beginning two months before, becoming progressively worse, and was aggravated by inclement weather and locomotion. Soon after the onset of pain, the patient noticed redness and moderate swelling of this toe.

The present illness dates from a year ago, when he experienced a burning sensation in the sole and all the toes of the left foot, starting originally in the big toe, spreading to the others. While undergoing treatment for this condition, he developed intermittent cramps in the left calf after walking (intermittent claudication). This symptom persisted up to and including the time he was admitted to the hospital. There were no constitutional symptoms.

He had pneumonia twenty-two years ago with hemoptysis, the entire illness lasting four months. He has been troubled with cough and expectoration for the past fifteen years. Two months after recovery from influenza, three years ago, he suffered from an attack of acute rheumatic fever and from that time, for a period of one year, he had palpitation of the heart every morning lasting about fifteen minutes accompanied by slight dyspnea and precordial pain extending occasionally to the left arm. He had a Neisser infection twelve years ago and denied lues by name and symptom.

He smoked moderately, about ten to twenty cigarettes a day, and subsisted on an ordinary full diet.

Physical examination, on admission, revealed a well nourished and well developed adult white male in the fourth decade of life, suffering acute pain. The eyes reacted sluggishly to light. There was a soft blowing murmur heard best at apex, accompanying and replacing second sound, heard best in sitting position, disappearing when breath was held; occasional extra systole heard. This latter sign has since disappeared. There was dullness at the right apex posteriorly, sibilant râles at end of inspiration heard over right chest posteriorly. The left small toe was red, swollen and tender with a small area of gangrene at the tip. The left big toe showed evidence of previous involvement by scaling and redness of skin. Other toes of left foot reddened, the typical rubor indicating a chronic compensatory capillary dilatation (1). The left foot was colder than the right. There was no pulsation of left dorsalis pedis obtainable, artery felt thickened and firm. Right dorsalis pedis artery was definitely pulsating. When both legs hung over the side of the bed, the left became markedly red over all toes and sole, limited sharply on dorsum.

Traces of lead were found in the urine on two examinations. Wassermann reaction was negative and blood chemistry gave normal figures. Spectrum was negative for tuberculosis.

The treatment consisted mainly of intramuscular injections of thirty per cent. sodium citrate solution five c. c. every other day, and alternate hot and cold foot baths.

His condition gradually improved as evidenced by relief from pain, sleeping through the night, lessened swelling and redness. However, two weeks following admission, pulsation in right dorsalis pedis artery had disappeared. The patient noticed cramps in the right calf for the first time the day previous, after walking, and pain in the toes of the right foot, especially the fourth toe. Amyl nitrite inhalations brought back pulsations in the right dorsalis pedis artery, but none in the left and at the same time it was noted, after taking the drug, that the capillary field showed more engorgment in the right foot than in the left foot. Treatment changed to intravenous administration of sodium citrate, 200 c. c., two per cent. every other day and amyl nitrite inhalations twice a day. Examination showed the right foot anemic, colder than the left, and the fourth toe quite blue at tip, apparently too early for compensatory capillary dilatation. There was absolute ischemia of both feet in the elevated position nor did blood return to the toes even after digital pressure applied to them had been released (compression test). As the feet were brought from the elevated (vertical) position toward the horizontal plane, the blood rush appeared earlier on the right side than on the left. On the right side, the more recently involved, an induced rubor was produced by depressing the limb, appearing earlier than the chronic rubor or erythromelia in the other foot which harbored the older process. For this reason the angle of circulatory sufficiency on the right side was less than on the left, 50 degrees on the right. 80 degrees on the left side. As the leg was slowly depressed from the elevated position toward the horizontal plane, a red color gradually replaced the blanched appearance. Assuming an imaginary line drawn through the limb in the vertical position, the angle formed by this line and the extremity moving from it toward the horizontal, at the first sign of return of blood denotes the angle of circulatory sufficiency (2).

When both feet were held in the dependent position over the side of the bed, the rubor of the left side became more pronounced but the right side was relatively unaffected and appeared quite anemic in contrast.

---

*Read before Lebanon Hospital Alumni Society, April 18, 1922.

Blood pressure taken at this stage of the disease at the right popliteal space was 130-85 and not obtainable on the left side. One month before he was discharged, the patient complained of a tingling sensation and purplish discoloration of his left thumb. I found that the pulsations in the left dorsalis pollicis had disappeared but after inhalation of amyl nitrite promptly reappeared. The inhalations were now increased to twice a day, intravenous sodium citrate and alternate hot and cold foot baths were still being used. When discharged from the hospital, he could walk without pain and the tingling sensation in his thumb was much reduced. At present he is employed as carpenter and painter in a ship building corporation.

In making the diagnosis, the possibility of this being either arteriosclerosis or Raynaud's disease was considered. Two x rays of the feet, negative for arterial and bone change, the sudden involvement of the right foot within twenty-four hours, the spreading of the disease to the left hand, the normal blood pressure with the difference in pressures noted in the popliteal spaces and the absence of renal involvement make arteriosclerosis highly improbable as a causative agent.

The pain and vascular changes are paroxysmal and spasmodic in Raynaud's disease and x ray quite early shows disturbance of outline of the bone (a neurogenic trophic phenomenon similar to those of the vascular system) neither of which changes were present in this case.

Regarding the rapid blood return noted on the right side after inhalation of amyl nitrite two main factors responsible for this phenomenon will be considered below. In the first place, the arterioles and capillaries in the right foot had not yet reached their full capacity for dilatation, the process being recent as compared to that on the left side where the response to further depressor influence by the drug was feeble because of their continued state of engorgement and dilatation. Secondly, the right dorsalis pedis artery resumed its function because it was unhindered by mural or perivascular fibrosis, late pathological changes which must have been present on the left side to have restricted its elasticity by decreasing its muscle elements (upon which the drug directly acts) and preventing free movement by adhesions to surrounding tissues.

From the study of our case, we are inclined to believe that notwithstanding our inability to check the progressive course of the disease as regards new sites of attack, it is frequently possible by appropriate treatment to ameliorate markedly its clinical manifestations at the local areas involved.

The Steinach Method as Applied to Women*

Preliminary Report

By HARRY BENJAMIN, M.D.,
New York.

The knowledge of Steinach's researches and of the operation that bears his name has spread considerably during the last two years and reports of cases of more or less successfully performed vasoligations are appearing in the medical literature in increasing numbers. I, myself, have operated up to the present time on sixty-two patients. The reports of these cases, however, are not the subject of this article, inasmuch as a number of them are too recent to warrant their publication. I should like to discuss briefly, the indications that led me to perform the operation and which—to my knowledge—have not been classified before, in exactly this manner. According to the indications for this endocrine surgery, I have divided my cases into three groups.

Group I.—Congenitial inferiority of the endocrine system, especially hypogonadism. In this group I have operated upon a certain number of relatively young men suffering from eunuchoidism and sexual impotence due to dyshormonism.

Group II.—Cases of acquired endocrine weakness, due in part to overwork and generally termed neurasthenia, principally affecting the adrenals. Only those cases were selected where marked endocrine disturbances were present, together with a hypofunction of the gonads. Most cases of so-called premature senility would fall under groups I and II.

Group III.—This last group comprises the cases of actual senility. The patients were men in the seventies and more.

As an interesting feature regarding the question of the class of people that have undergone the operation, I might add that nearly thirteen per cent. of my patients were physicians; among the remaining cases, there were three dentists, eleven professional men, twenty-seven business men, eleven laborers and mechanics, one municipal officer, and one artisan. Evidently in other reports on the Steinach operation, for instance, by Robert Lichtenstern, of Vienna, Peter Schmidt, of Berlin, and Knud Sand, of Copenhagen, similar statistics could be compiled. It seems, however, that among the reports available there are fewer professional men and decidedly fewer physicians.

Regarding the application of the Steinach method to women by x ray exposures of the ovaries and the regeneration of the female puberty gland, I present the following preliminary report of my own experiences. Other clinical reports on this subject are so far lacking in the literature, but I know from verbal communication that, for instance, Dr. Manfred Fraenkel in Berlin, has had quite remarkable results and is at present engaged in preparing their publication.

---

*Read before the New York Academy of Medicine, October, 1923, under the auspices of the German Medical Society.

The term female puberty gland was given by Steinach to those histological structures of the ovary which are held to be responsible for its internal secretion. There is still a great divergence of opinion in regard to these structures, and I shall therefore not go into the details of the different theories which have been advanced by the various investigators. However, there seems to be little doubt that the interstitial cells of the ovary, as well as the corpus luteum, are both hormone producing elements of the ovary.

In his book on *Rejuvenation*, published in 1920, Steinach devotes only a brief chapter to the method of the combatment of age in women. He mentions the possibility of transplantation methods, for which, however, great limitations exist, mainly on account of the difficulty in procuring suitable material. Reports of cases where such transplantations of ovaries were carried out are somewhat contradictory. For instance, Tuffier's experiences, reported in 1921, contain little encouragement for the homoplastic methods. Morris, however, as far back as 1906 reported quite successful operations.

Steinach has now conducted extensive experiments, together with Holzknecht, in Vienna, with a treatment of ovaries by x rays. Carefully exposing the ovaries of young guineapigs to x rays, a pronounced hypertrophy of the interstitial cells was produced which caused a corresponding premature maturity of the female secondary sex characters in those youthful animals. Apparently, a very strong stimulation of the production of gonadal hormones had been accomplished. Comparing the histological structure of the ovary on a section before and after x ray exposures, a marked degeneration of the follicular apparatus and a distinct increase in interstitial cells was seen. In connection with these animal experiments, Steinach asked Holzknecht to inquire about the state of health of those of his patients whom he had treated with x ray exposures (for tumors of the uterus, or climacteric hemorrhages), producing a therapeutic x ray castration. The inquiry revealed the fact that this form of castration was quite different from the surgical castration, since the expected signs of a quicker appearance of symptoms of senility were not noticed. Furthermore, the positive improvement in these women was so conspicuous that it could hardly be attributed alone to the cure of the original ailment, although this had generally been regarded as the cause of the beneficial result. Holzknecht reported that in these women the lassitude had disappeared and full physical and mental vigor had been restored; a decidedly more youthful appearance had been noticed, as evidenced in the better circulation and greater firmness of the skin. Considering the animal experiments, Steinach concluded that an unintentional incretoric stimulation of the ovaries had been produced in these patients, causing in turn a general stimulation of the entire endocrine system. Aside from the cure of the uterine trouble, this stimulation accounted for the remarkable clinical improvement. Steinach, therefore, as far back as in 1920, thought of the possibility of combatting age in women by the x ray treatment of the ovaries.

Within the last year and a half I have had a number of women treated with x rays, with the special purpose of combatting beginning or pronounced symptoms of age. Disturbances of the menopause have been treated quite frequently in recent years with x ray stimulation of the ovaries, and following Steinach's theories and suggestions, Groedel, in Frankfort, reported very good results. He believes that a stimulation dose for the endocrine portion of the ovary corresponds to the castration dose of the follicular apparatus. Thaler, in Vienna, likewise successfully used stimulation doses for the ovaries in cases of young girls with menstrual disturbances and amenorrhea in order to overcome their hypogonadism.

Only the first six of my cases date back far enough that I feel justified in reporting them, and I shall give you, very briefly, their clinical histories and the results that were obtained.

Regarding technic and the somewhat problematical and much discussed stimulation dose, this much can be said, that a stimulation dose of the ovary is considered by many röntgenologists about one seventh to one tenth of the socalled erythema dose.

In another series of fifteen cases, the patients were treated somewhat differently as to details. I do not feel justified in reporting their clinical histories as yet, since they are of too recent date.

CASE HISTORIES.

CASE I.—The patient, an educator, sixty-four years old, for several years had complained of an increasing lack of mental activity; power of concentration was waning, also imaginative ability. Mental sterility would perhaps best sum up her chief complaints. Outside of occasional sleeplessness requiring veronal, there was no physical disability or physical complaint. She began to menstruate at fourteen years of age, had practically always been regular, except during acute illnesses. The menopause had occurred seventeen years ago. Examination was negative as to any pathological conditions; her pulse was 50; blood pressure 146 systolic, 100 diastolic; skin reaction was almost lacking; weight, 156 pounds.

Treatment was begun in February, 1922, applying a stimulation dose to the right ovary alone. Three more treatments were given at intervals of one week, exposing right and left ovaries alternately. The patient felt very dull and tired for a few days after each treatment. About six weeks after the first treatment, this very intelligent patient, not hysterical at all, stated that she slept better than in many years; that she felt her brain clearer; that she had begun to do considerably more work, and that she felt more "sustained" in it. New ideas had come to her "like a flash," as rarely before. Examination showed a slight increase in weight; pulse 76, blood pressure 130 systolic, 85 diastolic. Skin reaction was red with faintly white borders. During the following months the patient was unusually active, working intensely from ten to twelve hours each day—a strain which she had not been able to endure in many years. She stated that she had regained her power of concentration and that her memory was distinctly better. In June, the patient received another treatment, a stimulation dose to the right ovary; the same, two weeks later, to the left. She was examined again in August, about five months after the completion of the first series of treatments. She felt very well and her friends had remarked upon her healthy appearance. Her weight was the same; blood pressure, 125, 85. She said she had distinctly more endurance, adding that "nothing could tire her any more." In March, 1923, a year after the treatment, her condition was unchanged and satisfactory in every way.

Case II.—This case is less characteristic because the patient, a widow of forty, in charge of a large dressmaking establishment in the West, was compelled to leave New York after she had received only one treatment, in April 1922, consisting of a stimulation dose to the left ovary only. The patient complained of a continuous feeling of exhaustion, being compelled to work hard and under a great nervous strain. She always felt tired and required about ten hours sleep daily. For several years her memory was rather poor and her hair had been turning grey during the past six months. She felt physically unable to perform the task which she had set for herself. Menses began at thirteen, had always been normal and were still regular, and of three days' duration. Examination did not reveal any special ailment. She gave an impression of being very nervous; reflexes were greatly exaggerated; pulse 82; blood pressure, 120-80; weight, 122½ pounds. There was pronounced tremor of the eyelids. In August, about four months after the treatment, the patient wrote that the reactions from the treatment had been very gratifying for a while. Several weeks after taking it she began to feel unusually well, but it lasted only a short time. The improvement, during which she felt "wonderfully well and strong," persisted for about a month, and then began gradually to wane. At the end of August she felt almost as tired as before the treatment. Weight was increased three pounds; pulse was 68; blood pressure, 110-75. Her reflexes had not changed. Her menstruation was not affected. Whether a proper administration of the method by giving several treatments would have produced a more lasting effect seems probable. It is, however, an open question.

Case III.—The patient was a teacher, aged fifty. She complained of stiffness in the limbs, pain in the back, great exhaustion, weakened memory, and great mental depression.

Her menses began at twelve and a half, had never been quite regular; menopause occurred seven months ago. The examination revealed a distinct soft swelling of the thyroid which she said she had had for many years. The heart was moderately dilated on both sides; pulse, 72; blood pressure, 115, 70. Skin reaction showed a distinctly white adrenal line; weight, 148 pounds. On July 22, 1922, one x ray treatment was given, applying a stimulation dose to each ovary. During the night after the treatment the patient had severe palpitation of the heart, which she said she had had only once before, when taking thyroid extract. A few days later she felt very well. The backache had disappeared and she said that she could walk without any discomfort —the first time in several months. She had a distinct feeling of physical strength and energy. Her skin reaction was faintly red; her pulse, 64. She was examined again on August 29th, about six weeks after the treatment. Her socalled rheumatic pains had entirely disappeared; she had occasional palpitation of the heart; was decidedly less tired in spite of being greatly overworked; the thyroid swelling was distinctly reduced. She looked unusually well, so much so that her friends remarked the favorable change in her appearance.

Some change in the endocrine functions (especially thyroid) seemed to have occurred, although, in this case, a certain probability exists that some of these changes were due to autosuggestion.

Case IV.—The patient was a widow, aged fifty-two. Her menopause had occurred four years ago, and since then she had suffered from rather frequent hot flushes, and had been told that her blood pressure was too high. Otherwise there were no complaints. Examination is generally negative, except a rapid pulse, 100 to 110, and a blood pressure of 190 systolic, 110 diastolic. Skin reaction only faintly red. During February and March the patient had had four treatments, receiving stimulation doses alternately to right and left ovary.

Upon reexamination in August, about five months after completion of the treatment, the patient said she felt brighter and more energetic. The hot flushes were still present, but decidedly less frequent. By dieting she had reduced her weight from 164 to 154 pounds. Her pulse was 76; blood pressure, 165 systolic, 100 diastolic. Skin reaction was distinctly red. Another examination only about a week ago, showed the same objective changes. She said that she felt better than in years, and more fit to do her work, especially in the last few weeks. The hot flushes were only rare.

In this case the possibility of an endocrine influence is present. Definite evidence, however, is lacking, since the patient, together with the treatment, underwent a change in her diet in order to reduce weight.

Case V.—The patient was a professional dancer, forty-eight years of age. She had had a nervous breakdown five years ago and had not entirely recovered since. She became tired too easily, lacked the necessary energy, and was very anxious to regain her full strength for her work. She had no other physical complaints. The examination was negative: blood pressure, 140 systolic, 100 diastolic; pulse, 72; skin reaction, red, quickly disappearing; weight, 135 pounds. The patient was still menstruating. During the months of March and April, 1923, five mild stimulation doses were administered, right and left alternately, and after the fourth treatment the patient expected her menstruation which, however, did not appear. She felt very well. Her pulse was 76; blood pressure, 130 systolic, 90 diastolic. She believed herself to be less nervously fatigued. The next month when her menses were due, they appeared in time and were not changed in character. She had noticed a distinct increased firmness in her breasts; felt unusually well; pulse and blood pressure were about the same; weight had increased two pounds. She looked exceedingly well, so much so that her husband said she looked as she did twenty years ago. He was so impressed by the change in her appearance that he himself, a man of sixty-one, decided to have the Steinach operation performed.

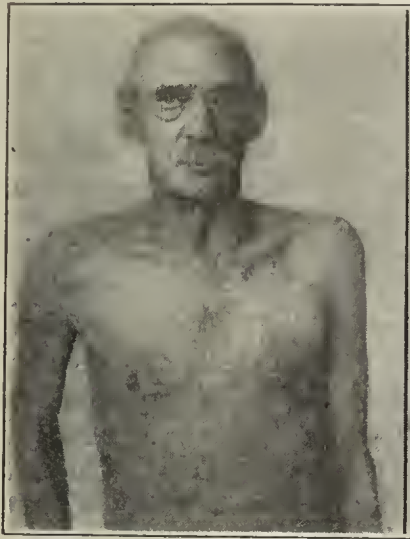

Fig. 1.

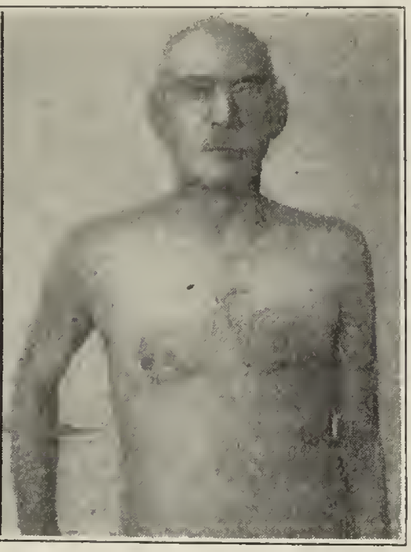

Fig. 2.

Fig. 1.—A merchant of sixty-eight years as he appeared before the operation, which was performed on October 4, 1920.

Fig. 2.—Shows the same patient two months after the operation.

Case VI.—A singer, aged forty-seven, complained of extreme nervousness, lack of ambition, waning memory and general mental fatigue. Her menopause had occurred seven years ago. Since then she noticed a general decline, especially in her voice. Twenty-two years ago the patient had part of her left ovary removed on account of a cyst. Examination was negative except for an increase in blood pressure which was 170 systolic, 90 diastolic; pulse, 72. Skin reaction faintly red.

Four treatments were given in April, treating both sides simultaneously with a stimulation dose. In August, about four months after the treatment was completed, patient said that she felt more balanced in her nerves, less emotional, but could not say much about her voice since she felt no desire to sing. She still complained of a lack of courage. Examination showed a certain decrease in blood pressure, 145 systolic, 96 diastolic, pulse, the same. Skin reaction distinctly red. Her weight had not changed.

In this case, too, an endocrine influence is very possible, although by no means proves, since the patient showed distinct mental inhibitions and the whole case apparently contained a strong psychic element. I advised that psychoanalysis should be used in addition.

In drawing conclusions from these six cases, I would advise great conservatism in their interpretation.

It is doubtlessly true that x rays change the histological structures and functions of the ovaries. It is also true that animals, after x ray exposures of their ovaries to the röntgen rays. Therefore, the development of their sex characters and, as far as women are concerned, it is true that castration symptoms can be produced by prolonged exposures of their ovaries to the Röntgen rays. Therefore, the probability seems very strong that x ray radiation is able to produce clinical changes in the sense of a regeneration and stimulation of endocrine functions. But after observing these six cases and considering the mentality of the patients undergoing a socalled rejuvenation treatment, I would recommend that one disregard whatever these patients tell or write of their subjective feelings, until more clinical experience is at hand; disregard their statements at least where no objective changes exist to corroborate them. Certain objective changes I have also reported and they should not be treated too lightly, inasmuch as an influence on the endocrine system working in this direction seems highly probable. But in order to feel certain about it, much more clinical material should be observed and over a much longer period. It is needless to say that the method is entirely harmless in the hands of a conscientious expert.

My reason for giving this preliminary report is merely to stimulate interest in "Steinachism" and to encourage further observations and tests along the lines which I have described in accordance with Steinach's theories and suggestions. A more detailed report of the technic and of my experiences will be presented in the future.

On the evening when this paper was read at the New York Academy of Medicine, four reels of a motion picture were shown, under the auspices of the German Medical Society.

These four reels constituted the main part of the socalled Steinach film, which was produced under Steinach's personal supervision by the scientific department of the Universum Film Corporation, Germany. This film depicts and explains Steinach's fundamental experiments and theories and shows the result of the Steinach operation on animals and human beings, and has as collaborators, men like Paul Kammerer, of Vienna, Peter Schmidt, Kurt Thomalla, of Berlin, and others.

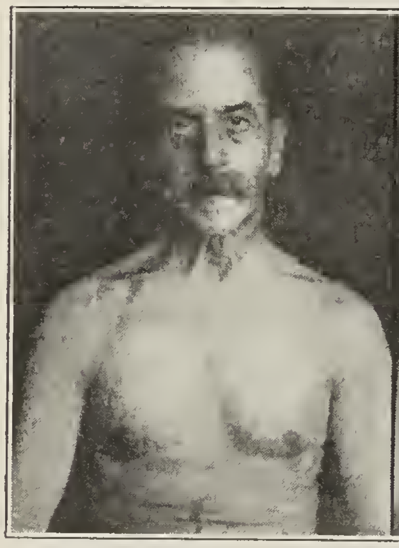

Fig. 3.

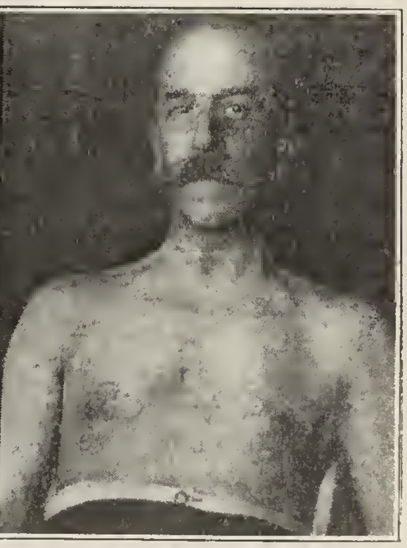

Fig. 4.

Fig. 3.—A controller of fifty-six years of age, who had the operation performed on October 5, 1920, "on account of premature symptoms of age, especially arteriosclerosis causing oppressions, pains and disturbances in gait. The patient was completely disabled and had been pensioned."

Fig. 4.—Shows the appearance of this patient four months after the operation. In the film it is explained that "he is again able to completely perform his duties and again actively in charge of his office." He is shown climbing mountains after he had been unable to walk before the operation.

The pictures reproduced here are two of those patients shown in the film who have, according to the explanation in the film, given "their explicit consent to demonstrate before the public pictorially the changes in their condition, and thus testify to the lasting effect of the operation."

Touching for the King's Evil*

By WILLIAM RENWICK RIDDELL, LL.D., F.R. Hist. Soc., etc.

Toronto, Ontario,

(Concluded from page 667)

The words of the eighteenth verse are repeated by the chaplain after every healing, till all the sick are touched, which being finished, the Gospel is continued to the end of the chapter. The second Gospel is then begun, taken from the first chapter of St. John, at the first verse. After the eighth verse, the surgeons, making three obeisances as formerly, come up the second time with the sick people; the Clerk of the Closet then on his knees delivers to the king the gold strung on a silk ribbon, and the king puts it about their necks, as the chaplain reads the ninth verse, "That was the true light, which lighteneth every man which cometh into the world," which he repeats as each receives the gold. The Gospel is then continued, ending with the fourteenth verse. The Gospel ended, the chaplain, with the rest of the people on their knees, pronounces these prayers:

> "Lord, have mercy upon us.
> Christ, have mercy upon us,
> Lord, have mercy upon us."

These are followed by the Lord's Prayer, and after it these versicles, the responses being made by those that come to be healed:

> Versicle, "O Lord, save Thy servants,"
> Response, "Which put their trust in Thee.
>
> "Send help unto them from above;
> And evermore mightily defend them.
>
> Help us, O God our Saviour;
>
> And for the glory of Thy Name deliver us; be merciful to us sinners for Thy Name's sake.
>
> "O Lord, hear our prayers;
> And let our cry come unto Thee."

Then the chaplain reads this prayer: "O Almighty God, who art the giver of all health, and the aid of them that seek to thee for succour, we call upon Thee for thy help and goodness, mercifully to be showed to these Thy servants that they being healed of their infirmities, may give thanks to Thee in thy Holy Church, through Jesus Christ our Lord. Amen."—and concludes with the Gratia Domini.

The ceremony over, the Lord Chamberlain and two other nobles, having brought up linen, with a basin and ewer to wash the king's hands, he takes leave of the people, "and they joyfully and thankfully do every one return home, praising God and their good king."

If there was any change made by James II, it was immaterial.

The numbers attending the Healings in these two reigns were almost incredible. Charles alone is said to have touched a hundred thousand persons. The records show that between 1668 and 1685 the number of touch pieces or medals was 78,662, and their value £34,942 4s. 2½d.; and an official record of those actually touched shows 90,798. It seems certain that the numbers presenting themselves for healing varied according to the popularity of the king for the time being; activity was promoted also by propaganda—"In less than eleven months of James's reign and for a period during which the Catholic movement fostered by himself was in full progress, no less than 14,364 persons are stated to have sought miraculous relief at his hands five times more favorable than his adored brother could ever boast of"—and a respectable authority says that James touched more than 6,000. But James was ever of frugal mind; he reduced the average value of the medals from ten shillings, as it had been in the time of Charles, to five shillings, and thus provided "for the requirements of a fictitious popularity without having recourse to an increased expenditure" (72). It was during the reign of James II that the tragedy occurred which is recorded by Evelyn in his diary under date February 28, 1684: "There was so great a concourse of people with their children to be touched for the evil that six or seven were crushed to death by pressing at the chirurgeon's door for tickets" (73).

The Revolution of 1688 placed King William III on the throne; he was asked to touch, but declined, referring the supplicants to the Stuart at St. Germain (74).

But if he declined, another but less fortunate claimant of the crown, did not. The Duke of Monmouth, natural son of Charles II, who led the rebellion in the West against his uncle, attempted to establish his legitimacy by touching. In the proceedings before the Court of Judiciary, Edinburgh, against the Duke of Buccleuch (Monmouth's father in law) and others for high treason (1685, 1686), "the criminall letters raisit at the instance of Sir George M'Kenzie of Rosehaugh our soveraigne lord's advocat" charged that on Monmouth taking "upon him to be a King . . . he commanded as King . . . and touched off the King's Evil and did exercise the other functions off royall dignitie" and "Captaine Anthony Buyse, latlie captaine in the duke of Brandenburgh's service aged threttie years or therby" did solemnly "depon" that he "saw him tutch for a disease which he understands since they call the King's evill" (75).

Queen Anne succeeded William of Orange; she was a Stuart and had no qualms about her gift of healing. She began to touch shortly after her accession in 1702, and continued the practice until the last year of her reign, 1714. The last occasion of which I have seen any record was within three months of her death. The newspapers of the day say that on March 30, 1714, Queen Anne touched two hundred persons; and among these it is known was Samuel Johnson, then about four and a half years old (76).

Anne was the first sovereign to have the Office of Healing inserted in the Book of Common Prayer. While it has been stated that it appears in a Prayer

---

*Read before the Toronto Academy of Medicine.

Book of 1703 folio, the first that is extant containing it is of date 1706. The latest in English is 1732 but a Latin version is found as late as 1759 (77).

Queen Anne's form differed a little from that used before her time; first a prayer, then the Gospel, Mark xvi, 14-20; then the Kyrie; then follows the Lord's Prayer, then the patients one by one presented to the queen upon their knees and as every one is presented and while the queen is laying her hands upon them and putting the gold about their necks the chaplain that officiates turning himself to Her Majesty, says these words, "God give a blessing to this work and grant that these sick persons on whom the queen lays her hands may recover through Jesus Christ our Lord"; then a further responsive prayer, a collect, and an address by the chaplain to the sick followed by the benediction, all in English (78).

On Queen Anne's death in 1714, George of Hanover succeeded; though the Office continued to be printed in the Prayer Book for some years (79) with simple changes from "the Queen" to "the King," etc., the ceremony never was again performed by a sovereign.

But while the abnegations of William III. and of the Georges were in full force the gift was not in abeyance nor did Queen Anne have a monopoly. James II. touched at St. Germain, as did his son the Old Pretender after him. The Young Pretender, Charles Edward, also touched at Edinburgh during his occupation of that city in the rising of '45. The Cardinal of York, who assumed the title Henry IX., on the death in 1788 of his brother, also claimed the gift and he is said to have exercised it (80).

The first royal bounty specifically allotted to the touched was almost certainly the angel or angel noble first coined in 1465 by Edward I.; this continued to be coined until the times of Charles I. The coin copied the device of the French gold coin *angelot* or *ange,* first struck by Louis XI—the Archangel Michael standing upon and piercing the Dragon; on the reverse was a ship on the waves with sails set. The coins differed in size and value from time to time and the inscriptions also changed. On the restoration, the angel being no longer coined, medals called "touch pieces" of less value were substituted; these were pierced to allow of a white ribbon being inserted whereby the king might hang them on the neck of the patients.

The touch pieces of Charles II. were of gold; James II. had also gold pieces but smaller and less valuable; he also had silver pieces, and so far as known the Pretenders and York also employed silver. Queen Anne used only gold.

These medals differed slightly in minutiæ, from time to time the device of Michael standing upon and transfixing the Dragon and the device *Soli Deo Gloria.* The reverse had the ship on the waters with sails set, also differing in minutiæ. The ship is in full sail in those of Charles II., James II. and Anne; the Old Pretender James III., the Young Pretender, Charles Edward, and Henry IX. have the ship taken aback, perhaps symbolical of their unhappy estate. In one of the pieces of the exiled Stuarts the device is the rose, thistle and shamrock, on the reverse is a representative of a hand from heaven coming down upon four heads and the words "He touched them," the motto being completed on the other side "and they were healed."

Of the efficacy of the royal touch there is overwhelming evidence, and it is proved as far as such a matter can be proved. The number running into the hundreds of thousands touched alone indicates some success, but this may be in part due to the gold or silver received; and in any case is not satisfactory evidence. Nor can we place much reliance upon the certificates of churchmen of high or low degree, such as Archbishop Bradwardine of the time of Edward III., Dean Tucker of Queen Elizabeth, Archbishop Sancroft of Charles II., Bishop Bull, Bishop Douglas, quoted by Hussey. They are largely influenced by a priori considerations. But men of the highest standing in the medical profession, from John of Gadsden down, are witnesses who cannot be contemned.

John of Gadsden, the father of English medicine, in the reign of Edward II. advised recourse to the touch in desperate cases, as the kings had the power of curing it (81). John is sometimes unkindly called a quack but he was the first Englishman employed as a physician at court, being appointed Royal Physician-in-Ordinary, by Edward II.; and he was quite abreast of the existing medical science. I pass over the certificate of Sir John Fortescue, Chief Justice in the times of Henry VI. (82), and come to another physician, Andrew Borde in the reign of Henry VIII., a physician of eminence, educated at Oxford, a graduate of Montpellier in medicine (83), who says: "For this matter, let every man make friendes to the Kynges Majestie, for it doth perteyne to a Kynge to helpe this infirmitie, by the grace of God, the which is geven to a king anoynted. But forasmuch as some men doth judge divers times a fystle or a French pocke to be the king's evil, in such matters it behoveth not a kynge to medle withall."

William Clowes (the elder), in the time of Queen Elizabeth, surgeon of St. Bartholomew's and Christ's Hospitals, a practitioner of the highest standing, says that this disease was "miraculously healed by the sacred hands of the Queen's most royal majesty, even by divine inspiration and wonderfull worke and power of God above man's skill arte and expectation" (84). And he gives a very remarkable instance of the cure by royal touch of a German who had been thirteen months his patient (85). Richard Wiseman, serjeant-surgeon to Charles I., surgeon-in-ordinary to Prince Charles, and subsequently on the Restoration appointed surgeon in ordinary for the person of the king, Master of the Barber-Surgeon's Company (corresponding to the present Royal College of Surgeons), gives the evidence of an eyewitness: "I myself have been a frequent eyewitness of many hundreds of cures performed by His Majesty's touch alone without any aid of chirurgery . . . from the several parts of the nation . . . also from Ireland, Scotland, Jersey and Guernsey . . . the weakness of our ability when compared with his Majesty's who cureth more in any one year than all the chirurgeons of London have done in an age" (86).

John Browne, already mentioned, surgeon in ordinary to Charles II., went into the matter very fully both historically and practically; he describes many wonderful cures about which he has not the slightest doubt (87).

The much more celebrated physician, Sir Thomas Browne, of Norwich, does not in his well known *Pseudodoxia Epidemica* make mention of healing by the royal touch but from what is said by John Browne, it would appear that he believed in it (88). A little later there can be no kind of doubt as to the belief of Dr. Daniel Turner. He relates several cures by Queen Anne after he and his coadjutor, Charles Bernard, serjeant-surgeon to the Queen had failed, and adds: "It is the misfortune of some to miss of their cures after much pain and great expense, yet it hath been the good luck of others to obtain one in this particular disease . . . I mean by the royal touch" (89).

Perhaps the most satisfactory, as it is the most extensive, account is given by William Beckett, F.R.S., surgeon and antiquary, surgeon to St. Thomas' Hospital and an author of repute. Far from being a credulous man, he was skeptical of the actuality of the cures; but he was convinced by the citations from the records furnished him by the elder John Austin, Garter King at Arms, and his own investigations of the antiquity of the practice. He is not convinced that it was the touch which healed but he considers it impossible to prove the cures supernatural or miraculous (90).

The evidence of the efficacy of the touch of the French kings is equally conclusive, but it is quite too long to set it out in this place.

There were always sceptics. Let me give an example or two. Samuel Pepys in his *Diary* under date of November 2, 1660, says: "By chance Mr. Holliard called at dinner time and dined with me, with whom I had great discourse concerning the cure of the King's Evil which he did deny altogether any effect at all" (91). Pepys' own opinion will appear from his entry for 1661, April 13 (day before Easter) "So to Whitehall again and met with my Lord above with the Duke; and after a little talk with him I went to the Banquet house and there saw the king heal, the first time that I ever saw him do it; which he did with great gravity and it seemed to me to be an ugly office and a simple one" (92).

Nor were the sovereigns the only successful practitioners of this method. Mention may be made of John Leverett; he was a gardener who took it upon himself to cure the King's Evil and he touched many. William Clowes (the younger), sergeant surgeon to King Charles I., and Master of the Barber Surgeons Company, brought him before the Star Chamber, October 20, 1637, and was directed by the lords in that court to lay the matter before the College of Physicians. Leverett appeared before the College, November 3, 1637, and stated that he had cured by touch alone King's Evil, dropsy, fever, agues, internal diseases and external sores, and said he was a seventh son. On inquiry made it turned out that he was a fourth and not a seventh son. Thomas Clowes and two other surgeons of London certified that his cures were impostures, and it appeared that he "enticed great lords and ladies to buy the sheets he had slept in and deluded the sick with false hopes." Leverett was stopped, but I think he did effect cures (93).

Shortly before Leverett's time, one James Phillip Gaudre, Knight of St. Lazare in France, prisoner for debt in the King's Bench Prison in London, took upon him to touch for the King's Evil; he was examined by Sir Thomas Richardson, Chief Justice, and alleged that he had cured many poor persons of the King's Evil, and some after being touched by His Majesty; he had used his skill in France before coming to England; he was the youngest of seven sons. The Chief Justice acquitted him of sorcery and fraud but reported that he was in contempt for taking upon himself a royal function (94).

The well known case of Valentine Greatrakes and his cures by touch will occur to everyone, "A gentleman, a member of the Church of England, of great honesty and exemplary sobriety, who is said to have refused any gratuity for his services," he performed marvelous cures of the King's Evil and afterwards of ague, epilepsy, convulsions, palsy, deafness and other complaints, all indeed "peculiarly under the influence of the nervous system." This was in the reign of Charles II. (95).

A still more recent case not wholly unlike the touch, is Perkins' Tractors, the story of which is familiar to everyone. There is not the slightest reason to doubt the good faith of Perkins or his patients. Dr. Elisha Perkins, of Norwich, Connecticut, thought he had discovered a new healing instrument in two rods, one of steel and the other of brass. The affected part of the body was stroked with the rods; and many cases of remarkable cures of rheumatism and of some of the neuroses were reported. Many medical men certified to the efficacy of this treatment and it became very popular in England. Dr. John Haygarth found by experiment in the Bath Hospital that rods of wood were quite as effective if the patients were not undeceived; and though a "Perkinson Institute" was established in London the practice gradually dwindled to complete disappearance. But it was successful while it lasted and was believed in (96).

There can, in this age of the world, be no difficulty in arriving at the truth. First, let us see what scrofula is.

Until but the other day it was considered a specific disease distinct from all others (97); it is now, of course, recognized as a form of tuberculosis. In many cases, the patients need but to be let alone to cure themselves; in most cases, cures are accelerated by change of scene, expectation, imagination, hope—all cases of cure were of this character.

And the touch was by no means always successful. Dr. Johnson suffered all his life from one form or another of the disease, and Hussey in text and manuscript notes gives a certain instance of speedy mortality of which there must have been thousands. In the Parish Register of Stanton St. Johns' near Oxford is an entry, 1705, March 25, "I gave a certyficate concerning Ralph Gilbert's son, Ralph, not being formerly Touch'd for ye King's Evil"—then there is a burial entry June 13, 1705, of "Ralph ye son of Ralph Gilbert day labourer and Elizabeth his Wife"—he was about twenty years old. (In the same registers we have Thomas, son of Thomas and Amy Grant, receiving a certificate February 25, 1684, and being buried sixty-one years later, March 27, 1745, aged seventy-three years).

The power of the imagination is almost unlimited. For example, among the Athenians many a man died of drinking bull's blood, the idea of the poisonous quality of which has not the slightest physiological foundation (98). So the effects of certain alleged medicines; and I instance the famous Mithridaticum which was a sovereign antidote against all poisons; it was discovered by Mithridates, King of Pontus, and with it he successfully defied all attempts to poison him. The prescription was found among his papers by Cn. Pompei and is given by Pliny: "Take two dry walnuts, two figs, twenty dried leaves of rue, add a little salt, take on an empty stomach. On the day this dose has been administered no poison can take effect." This was fully believed in until the end of the Middle Ages.

It is worth while to quote the opinion of the wise old Richard Mead, Colleg. Medicor. Lond, at Edinburg, Soc. Reg. Societat. Sodal, et Medicus Regius; he in his *Monita et præcepta Medica,* published in London, 1751, a book which it is a delight for all to read who have not forgotten their Latin, says:

"Yet there is in this disease, however nonresponsive to treatment it may be, the notable characteristic, that often by reason of change in age or habit of the body—especially in youth—it spontaneously comes to an end so that the original health is restored. It was this fact, in my opinion, which first brought into vogue what they call the royal healing touch. For when astute men apprehended this feature of the disease, they easily and naturally came to the conclusion that they would make the kings favorable to the practice if they could persuade them to make experiment of their power with solemn ritual accompanied by prayers of priests, whereby they would be able to gain the reverence of the people toward themselves and if the event were successful, prove that they held the throne by divine right. It is not at all to be wondered at that the statements had full credence given them and that some times the kings themselves believed that they had this power of healing as a gift from heaven for

> Nihil est, quod credere de se
> Non possit, cum laudatur, dis aequa potestas
> Juvenal, Sat. IV, v. 70.

"And the world wishes to be deceived—the event occasionally fell out as wished for, to which result the force of imagination which has very great influence in the curing of disease, contributed not a little. This favor our kings (except when some more enlightened prince happened to occupy the throne) humanely conferred upon their credulous people daily. The kings of France, indeed, boasted that they had this gift from Heaven before ours.

The author's notes will appear in his reprints.

Practical Applications of Basal Metabolism*

By JESSE G. M. BULLOWA, M.D.,

New York.

Before any diagnostic procedure can be introduced into everyday practice with any prospect of permanence, it must meet certain conditions in respect to the procedure and to the information it provides. The procedure must be without pain or distress to the patient, require little time, and not be too costly for general application. These conditions are all met by the simplified Benedict method of determining the oxygen consumed in a definite time and calculating the calories for surface area and age, with the help of tables DuBois developed by means of the elaborate respiration calorimeter.

The patient comes to the office in the morning, fasting, twelve to fourteen hours after an early meal the night before. There, after resting one half to one hour, the test is performed in a quiet room. The test and its control, with calculations, require about one hour. The cost of the material is insignificant. Oxygen and calcium carbonate are consumed. The apparatus is not unduly costly and simple types of apparatus, which is essentially a water sealed spirometer, may be purchased or even improvised from material readily assembled from old gas masks and sheet metal with the aid of a tinsmith. The performance of the test requires some expertness and practice, but less actual manual dexterity and skill are necessary than is expected of every competent physician in physical examination by palpation, percussion, and auscultation. The results must be interpreted with insight into attending circumstances, but then, no medical data can be inserted into an adding machine to furnish the answer.

Basal metabolism determinations replace no other clinical observations, but they do furnish an additional physical sign which is rapidly entering all complete examinations where indicated. For a physical sign to become established it must either give information which is pathognomonic or which is susceptible of precise interpretation in the presence of other phenomena. The fact that the information may sometimes be inferred from other physical evidence does not detract from its value, because it is upon corroboration of various sorts of evidence that we base a diagnosis.

The actual determination of basal metabolism furnishes a quantitative measure of the change it reveals. There are characteristic clinical manifestations of disturbances in the metabolism of fat and phosphorus, revealed by the distribution and accumulation of fat; in the metabolism of lime, by the shape and density of x ray shadows; and in the metabolism of sulphur, by the condition of the skin, hair and nails, as well as in the basal metabolism or the metabolism of oxygen used as an indicator, revealed by disturbances of the pulse rate and tissue turgor. The conditions influencing these metabolic changes are many. Only the basal metabolism is susceptible of ready quantitative and immediate determination at the bedside.

---

*Read before the Medical Association of the Greater City of New York, March 19, 1923.

Among the factors governing the changes in the metabolism of these various substances are the hormones produced by the ductless glands. Students of the endocrine organs have collected an enormous mass of painstaking observations. Unfortunately they have also elaborated a system of uncritical inferences from this material so that the literature reads more like fiction than science. On this account an exact quantitative method of observation has quickly established itself as a useful corrective for the tendency to romance.

I wish it had been possible to report that changes in basal metabolism were pathognomonic. Unfortunately this is impossible, but the determination of basal metabolism has been established as a useful clinical guide in a number of conditions. The field in which it has proved most useful is in the diagnosis and treatment of diseases of the thyroid. The active principle of the thyroid—thyroxin—causes a definite increase of metabolic change under basal conditions. This is, however, quite different from the assertion that increases in basal metabolism in thyroid disease are due primarily to excessive thyroid secretion. The experiments of Marine have shown that it may be the unantagonized thyroid secretion which is important. There may be other as yet undiscovered factors.

The determination of basal metabolism is helpful under three circumstances. The basal metabolism may be normal in the presence of symptoms which from their frequent association with hyperthyroidism have themselves been attributed to excess of circulating thyroxin. I refer to symptoms due to overaction of the vagus sympathetic system and its results. The separation of the Graves syndrome as a distinct condition from hyperthyroidism is an important trend in modern medical thought, made possible by the work of DuBois, Kendall and Gudernatsch. Enlargements of the thyroid, or goitre, occur in adolescence, frequently with other symptoms which formerly were considered sufficient to make the diagnosis of incipient exophthalmic goitre. In these cases the basal metabolism is usually normal. They are relieved by the administration of iodine. These goitres should not be removed; the patients need all the thyroid secretion available. Definite goitres may occur with the symptoms of Graves' disease and the basal metabolism may be normal. The symptoms of Graves' disease may occur without the presence of goitre and the diagnosis of an aberrant hypersecreting thyroid may depend upon increased basal metabolism determination. Increase in the basal metabolism is evidence of an excess of available thyroxin, except in conditions which are readily distinguished from it, such as erythremia and leucemia.

The presence of low basal metabolism occurs in pituitary deficiency, in cretins and in myxedema. It is especially important in the diagnosis of the more obscure cases of the last named condition. Patients frequently present themselves suffering from mild Graves' symptoms, a tremor, slight exophthalmos, nervousness and acceleration of the pulse. Sometimes there is a slight goitre. There may or may not be a story of recent accumulation of fat. In the past these patients were regarded as suffering from hyperthyroidism, dysthyroidism, or hyperhypothyroidism. Many of them show a diminished basal metabolism. Such a patient presented herself recently. She suffered from severe headache associated with menstruation. She had been generally regarded as a subjct of hyperthyroidism. She might have been. At present her basal metabolism is twenty-five per cent. below normal.

The simultaneous hyperhypothyroidism conception must yield to definite evidence of thyroid deficiency revealed by the basal metabolism test. There is no evidence, experimental or clinical, to support the view that such a patient is suffering from a change in the thyroxin, as many such patient's have normal basal metabolisms and the symptoms might exist without implication of the thyroid.

Large colloid goitres are frequently associated with normal or subnormal basal metabolism. They should not be removed except when they produce menacing symptoms from pressure. To attempt thyroid surgery without basal metabolism determination seems, at the present day, not only utterly unscientific, but dangerous to the life of the patient and the reputation of the surgeon. It has been shown that the manifestations of hyperthyroidism may be reduced by exposure to the x ray. To destroy thyroid tissue by exposure to x ray without justification from the evidence of basal metabolism tests seems equally culpable.

In the treatment of myxedema, basal metabolism determinations are a measure of efficient doses of thyroxin. For such patients, repeated determinations are as important as any other observation. In the treatment of patients by x ray or by surgical ablation, whether by arterial ligation or by actual removal of the gland, the extent of the procedure should be estimated from the amount of the disturbance in the basal metabolism. The basal metabolism is roughly an evidence of thyroxin overproduction, as well as of surgical resistance. The published charts and my own experience lead me to believe that the return to a normal basal metabolism after thyroidectomy is not rapid, and I have seen almost identical courses in patients thyroidectomized and in those treated by the administration of adrenal cortex. Emphasis should be placed on the importance of not giving to the evidence of basal metabolism any finality in the diagnosis of primary thyroid disease. Increase or deficiency in thyroid function is all it shows and this may be in response to influences arising elsewhere rather than from inherent thyroid disease. Aside from the treatment of thyroid disease, basal metabolism determinations are of value as a measure of the efficiency of x ray treatment in myelogenous leucemia.

Another condition in which basal metabolism determinations have been of service are the nephroses. Epstein and Lande have shown the association of diminished basal metabolism, edema, and a high cholesterinemia. Oskar Frankl deems the cholesterinemia of small importance. Thyroid extract is of value in treating obstinate edemas in this condition and the high nitrogen diet, originally recommended by Widal, may act in them by stimulating the thyroid. Empirically, Eppinger found thyroid useful in this condition. Basal metabolism determinations now offer an additional aid to accurate diagnosis and treatment, and indeed segregate the edemas amenable to thyroid therapy.

In obesity, basal metabolism determinations apparently establish the infrequent association of lowered available thyroxin. Other factors seem to be involved in the increased fat storage which may be preferably counteracted by dietary restriction. When thyroid is fed it should be done only with the control of frequent determination of the basal metabolism. No signal assistance has been furnished by basal metabolism determinations, with oxygen as an index, in diabetes. The respiratory quotient may be calculated, however, and this is of diagnostic importance, especially in conjunction with the use of insulin.

Unquestionably the increased use of basal metabolism apparatus in other conditions will bring to light still further practical applications and no one can foretell the full measure of its usefulness in the exact diagnosis of clinical syndromes and the consequent aid to therapy. I trust that I have shown that basal metabolism determinations are already a necessary feature of everyday clinical practice.

62 West Eighty-seventh Street.

Provision for the Care of Convalescents in New York City*

By THE PUBLIC HEALTH COMMITTEE OF THE N. Y. ACADEMY OF MEDICINE

Provision for the care of convalescents constitutes an indispensable complement to hospital treatment. In New York City the need of institutional convalescent facilities has been acutely felt because of the economic and home conditions of a large portion of the population. Individual philanthropists, as well as organized charity, have responded to the need and established convalescent homes which are maintained and operated independently of the hospitals. Only seven of the sixty-two convalescent institutions are operated by hospitals; two of these are associated with hospitals for children, two with orthopedic hospitals, and three with general hospitals, two of these three belonging to one institution and devoted almost exclusively to work for child patients, the other operated by another general hospital and open during the summer only.

Since the costs of construction and maintenance of convalescent homes are considerably lower than those of hospitals, it has been frequently urged that the hospitals establish country branches to which convalescent patients could be sent to receive proper treatment and supervision until they have been fully restored to health and economic usefulness. Such country branches would not only be advantageous to the patients whose restoration to health, both physical and mental, could proceed under the same general direction as in the hospital where they were treated, but would also make more beds available in the city for cases of acute illness, as the average length of stay of the patient in the hospital would be shortened by transfers to the country branch. Several general hospitals have had the establishment of such homes under consideration. One of the reasons why further action has not been taken is the uncertainty as to whether such a convalescent home, with its patients limited to those of one hospital, could be economically maintained throughout the year; and the second reason is the existence of a large number of convalescent homes with an average utilization of not much more than seventy per cent. of their effective capacity. Furthermore, the whole problem of convalescence has not been attacked in a scientific manner, either in its medical or its community relationships.

CONVALESCENT NEEDS.

The recent war experience has led some observers to the conclusion that "the average patient who has been sufficiently ill to require the average length of stay of three weeks in a hospital for acute diseases, has also been sufficiently ill to require an additional average period of three weeks under observation in a convalescent home or hospital." (1)

Not only hospital patients but others who pass through a period of serious illness require proper environment for their convalescence. Since, however, it would be utterly impractical and prohibitively expensive for the community to provide convalescent facilities for all those recovering from sickness, the patient's home must serve the purpose in the large majority of cases, and social service agencies have a great opportunity to aid the families with whom they come in contact to make this convalescent period in the home as effective and helpful as it can be made by intelligent supervision and guidance. There remains, however, a large number of patients who cannot obtain, under existing housing conditions, the type of care necessary for proper recovery. It has been estimated that for convalescent purposes the community should provide facilities equivalent to twelve per cent to fifteen per cent of its total hospital bed capacity. (2) On this basis, New York City with its 32,000 hospital beds (including private rooms in hospitals as well as proprietary institutions) would require from 3,840 to 4,800 beds in institutions for convalescents. Another estimate places the need at twelve per cent of all hospital patients, allowing ten per cent. for the hospital patients proper and two per cent. of this number for other patients. In New York City we have in round numbers 375,000 hospital patients annually; according to this estimate, 45,000 persons require institutional convalescence. The average stay of a convalescent patient is twenty-one days; each bed can, therefore, be used by seventeen patients in a year. On this basis, the total number of beds needed would not exceed 2,650. The various estimates undoubtedly have a sound pragmatic basis but cannot be more than suggestive of a norm, as the actual demand for facilities depends upon many variable conditions, such as the economic cycle of industrial prosperity and depression, housing conditions, the interest of hospital authorities in their patients, the activities of the social service departments, the prevalence of illness and other factors. The fact that the large majority of hospital patients are surgical cases, many requiring facilities which are nonexistent in the usual type of convalescent institution, is a factor which has not been seriously considered as yet in the staffing and equipping of convalescent homes. It should also be borne in mind that the convalescent homes, situated as they are outside the city limits, serve the outlying communities as well, and to that extent the facilities for the sick residents of the city are curtailed. A study of the domiciliary distribution of the patients indicated that in some of the institutions the proportion of those residing outside of New York City limits is considerable; in one instance, it was as high as sixteen per cent. of the total during a particular year.

---

*This paper was prepared by Edward H. Lewinski-Corwin, Executive Secretary of the Public Health Committee, and constitutes one of the sections of the study of hospitals made by the committee. The membership of the committee is as follows: Charles L. Dana, M. D., chairman; James Alexander Miller, M. D., secretary; Nathan E. Brill, M. D.; Samuel A. Brown, M. D.; Robert J. Carlisle, M. D., James B. Clemens, M. D.; Leland E. Cofer, M. D.; Rufus I. Cole, M. D.; Robert L. Dickinson, M. D.; Haven Emerson, M. D.; Lewis Fox Frissell, M. D.; S. S. Goldwater, M. D.; Royal S. Haynes, M. D.; John A. Hartwell, M. D.; Ward A. Holden, M. D.; L. Emmett Holt, M. D.; Walter B. James, M. D.; Charles E. Nammack, M. D.; Walter L. Niles, M. D.; Bernard Sachs, M. D.; Thomas W. Salmon, M. D.; Charles Hendee Smith, M. D.; Frederic E. Sondern, M. D.; M. Allen Starr, M. D.; Howard C. Taylor, M. D.; W. Gilman Thompson, M. D.; Philip Van Ingen, M. D.; Karl M. Vogel, M. D.; George B. Wallace, M. D.; Cassius H. Watson, M. D.; Herbert B. Wilcox, M. D.; Linsly R. Williams, M. D.

AVAILABLE FACILITIES.

It is sometimes difficult to draw the line between a convalescent home and a socalled fresh air home, as in many instances, the latter only take applicants who are below par in health, but who are not convalescent in the strict sense of the word. The line has been drawn as far as is possible, and the number of beds in institutions in or around New York City which are regarded as serving distinctly convalescent patients is 3,220. Of this number of available beds, 1,189 are for adults and 2,031 for children under sixteen. These figures of course are subject to correction at any time. Of the 1,189 beds reserved for adults, 339 or 28.5 per cent. are for men and 850 or 71.5 per cent. for women. The division of beds for children is approximately as follows: 566 for babies, 681 for boys and 784 for girls. Of the total number of beds available for adults, 559 are in institutions exclusively for adults and the remainder in institutions which take both adults and children. 1,314 beds out of a total of 2,031 for children are in institutions maintained exclusively for children. Of the total sixty-two institutions, forty-five are operated all the year round, thirteen only during the summer months, and four only during the winter. The seventeen part time institutions have a combined bed capacity of 857 beds, which on the basis of a four months' utilization in a year is equivalent to 286 available the year round. Our total convalescent bed capacity on the annual available basis does not exceed 2,650. With the exception of certain institutions for the care of children which admit only certain types of conditions, the convalescent homes do not specialize in any particular type of patients, except that many of them exclude mental and neurological cases, orthopedic patients unable to care for themselves, nontuberculous pulmonary cases with a disturbing cough and those requiring special diets or surgical dressings; in many institutions neither negroes nor adolescent boys are taken, the former because of race prejudice and the latter because of their unmanageability.

Aside from tuberculosis sanatoria which are not included in the group of institutions under consideration here, the greatest progress has been made in provision for sufferers from cardiac diseases, although the need in this connection has not been fully met. The need for convalescent care of orthopedic cases has been forcibly brought before the community, and provisions have been made to meet the demand to a certain extent. In some instances, it is difficult to draw the line between a convalescent and a chronic patient, and as the needs of the latter are entirely different from that of the convalescent patient, they are not discussed here.

Most of the convalescent homes do not publish statistics of conditions from which the patients convalesce and some of them do not even keep such statistics. It is, therefore, impossible to ascertain the extent to which certain types of cases are more adequately provided for than others.

An inquiry of the social service departments of the hospitals was made with a view of eliciting information as to the types of patients who are most difficult to place in convalescent homes. The replies received do not focus on any particular condition. The most frequently mentioned difficulties are encountered in placing neurological and mild psychosis cases, special diet cases such as nephritics and diabetics, and postoperative, gastric ulcer cases, adolescent boys, helpless and crippled children, mothers with children, and certain types of older men.

The following is a list of convalescent homes serving New York City with their bed capacities.

CONVALESCENT FACILITIES FOR GREATER NEW YORK—1922-1923

1.	Babies' Hospital, Summer Branch, Rumson, N. J.	55
2.	Bikur Cholim Convalescent Home, Mt. Vernon, N. Y.	25
3.	Blythedale Home for Convalescent Children,[1] Hawthorne, N. Y.	40
4.	Burke Foundation, White Plains, N. Y.	300
5.	Campbell Cottages (New York Hospital),[2] White Plains, N. Y.	80
6.	Caroline Rest (A. I. C. P.),[3] Hartsdale, N. Y.	114-120
7.	Children's Country Home (Assn.),[4] Westfield, N. J.	18
8.	Convalescent Home for Hebrew Children,[5] Rockaway Park, L. I.	Avg. 78
	Aftercare Home for Crippled Children,[5] Rockaway Park, L. I.	30
9.	Country Home for Convalescent Babies, Seacliff, L. I.	50
10.	Daisy Fields Home and Hospital, Englewood, N. J.	18
11.	Edgewater Creche, Englewood, N. J.	20
12.	Elizabeth Milbank Anderson House (C. A. S.), Chappaqua, N. Y.	175

13.	Gallatin Cottage (C. A. S.), Valhalla, N. Y. (See note on Kinderfold.)	50
14.	Gerald Ease, White Plains, N. Y.	15
15.	German Home for Women and Children, Coney Island, N. Y.	45
16.	Gould Farm,[6] Great Barrington, Mass.	12.5
17.	Greenview House, Bradley, N. Y.	14
18.	Health Home (C. A. S.),[7] Bath Beath, L. I.	230
19.	Hebrew Convalescent Home, New York, N. Y.	45
20.	Hill Top Camp (Presbyterian Hospital),[8] Hawthorne, N. Y.	32
21.	Holiday Farm, Rhinebeck, N. Y.	50
22.	House-by-the-Sea (Union Settlement), East Moriches, L. I.	25
23.	House of St. Giles the Cripple,[9] Garden City, L. I.	60
24.	Incarnation Winter Home, Lake Mohegan, N. Y.	28
25.	Isabella Home,[10] New York, N. Y.	56
26.	Jane Elkus Home (Free Synagogue), Oakhurst, N. J.	22
27.	Jewish Home for Convalescents,[11] Grandview, N. Y.	40
28.	Josephine Home, Peekskill, N. Y.	25
29.	Kinderfold (C. A. S.),[12] New Brighton, S. I. Goodhue Home, New Brighton, S. I.	10 3
30.	Loretto Rest (Catholic Charities), Cold Spring, N. Y.	16
31.	Lulu Thorley Lyons Home, New York, N. Y.	50
32.	(Bishop) McDonnell Hall for Convalescent Women, Commack, L. I.	24
33.	Maple Cottage, Peapack, N. J.	24
34.	Martha Summer Home, Ossining, N. Y. (See note on Kinderfold.)	6
35.	Martine Farm, White Plains, N. Y.	24
36.	Mary Zinn Home for Convalescent Cardiac Children, White Plains, N. Y.	41
37.	Mineola Home for Cardiac Children,[13] Mineola, L. I.	56
38.	Montclair Fresh Air and Convalescent Home, Verona, N. J.	36
39.	Moore (James A.) Memorial Home,[14] Seabright, N. J.	10
40.	Mountain Pass Farm (Friendly Aid Society), Hillsdale, N. Y.	36
41.	Neustadter Home, Yonkers, N. Y.	58
42.	New York Orthopedic Hospital, Country Branch,[15] White Plains, N. Y.	135
42a	Noyes Memorial Home (St. Mary's Hospital)[16] Poughkeepsie, N. Y.	30
43.	Pelham Home for Children, Pelham Manor.	
44.	Reed Farm, Valley Cottage, N. Y.	33
45.	Nichols Cottage, Valley Cottage, N. Y.	6
46.	Rest for Convalescents, White Plains, N. Y.	72
47.	St. Andrew's Convalescent Hospital,[17] New York, N. Y. St. Andrew's Rest, Woodcliff Lake, N. J.	average 26
48.	St. Eleanora's Home and Cottage for Convalescents, Tuckahoe, N. Y.	55
49.	St. James Convalescent Home, Norwalk, Conn.	20
50.	St. John's Home (Catholic Charities), Mamaroneck, N. Y.	25
51.	St. Joseph's Villa (Rest Home), Catskill, N. Y.	30
52.	St. Mary's Hospital Summer Home, Norwalk, Conn.	80
53.	St. Vincent de Paul Convalescent Home (St. Elizabeth's), Spring Valley, N. Y.	40
54.	Sarah Schemerhorn House (N. Y. P. E. C. M. Society), Milford, Conn.	50
55.	Seaside Home for Crippled Children, Far Rockaway, L. I.	65
56.	Solomon and Betty Loeb Memorial Home, Eastview, N. Y.	108
57.	Spring Valley Camp (Henry Street Settlement), Spring Valley, N. Y.	21
58.	Sunnyside Farm (Margaret and Sarah Switzer Inst.),[18] Manasquan, N. J.	40
59.	Surprise Lake Camp, Cold Spring, N. Y.	70
60.	Urban League Convalescent Home (for the colored), North Pelham, N. Y.	8
61.	Valeria Home,[19] Croton, N. Y.	124
62.	Wavecrest Convalescent Home, Far Rockaway, N. Y.	35
	Total	3220

[1] Blythedale Home for Convalescent Children: Until September 1922 at Hawthorne, N. Y., with forty beds; temporarily working in connection with Convalescent Home for Hebrew Children at Rockaway Park, N. Y., with twenty-five beds, until completion of new building at White Plains, N. Y., about September 1923, when fifty-eight beds will be available.

[2] Campbell Cottages: Will take boys of eleven or twelve sent by New York Hospital.

[3] Caroline Rest: Designed chiefly to meet the need of convalescent mothers with children, particularly the young mother with first baby. Facilities for children are divided so that there are about eighty-four to ninety beds available for babies able to run about and older children. Usually there are about 114 beds, but this number is sometimes brought up to 120.

[4] Children's Country Home at Westfield, N. J.: Until the spring of 1923 open during the summer months only; has at present a total bed capacity of forty-eight, about 36 per cent of which is used for children from New York hospitals.

[5] Convalescent Home for Hebrew Children: Accepts girls from six to twelve and boys from six to ten. Occasionally takes younger child of four or five but will not take a girl of eleven if mature.

[6] Gould Farm: Only a portion of the guests are convalescent, and there is no medical attendance. The figures estimated above cover the approximate number of beds used by New York City patients needing recuperative rest.

[7] Health Home: Has approximately five hundred beds, forty of which are used for nursery children on outings; fifty to sixty for crippled children, and 125 for mothers with children up to six years. It is estimated that about 175 convalescent children are provided for while the other one hundred beds are for children other than convalescent. By adding to the 175 convalescent beds an average of fifty-five beds for crippled, we arrive at the approximate figure of 230 given above. Plans are being discussed regarding the advisability of changing the policy by keeping the place open the year round with emphasis on convalescent needs in the winter and extra provision for mothers and children in summer.

[8] Hill Top Camp: For children with tuberculosis and occasionally from the cardiac clinic of Presbyterian Hospital, divides the summer care into separate periods for boys and girls which gives total number of beds thirty-two for each.

[9] House of St. Giles the Cripple: At Garden City, L. I., had thirteen beds for girls and twenty beds for boys prior to completion of new building in May, 1923, when provision was made for sixty children—tentatively thirty boys and thirty girls.

[10] Isabella Home: Is "mainly a home for the aged and the convalescent department (fifty-six beds) is a small part of the work of the Home."

[11] Jewish Home for Convalescents: Running far below total capacity of 140 possible beds.

[12] Kinderfold—Goodhue Home: Reserves an average of three beds for use of convalescent girls among those sent there for placing out. Martha Summer Home, also maintained by the Children's Aid Society, reserves six beds for those of the girls who need convalescent care.

[13] Mineola Home for Cardiac Children: Will accept a small boy of sixteen but will *not* take a large or overdeveloped (adolescent) boy of fifteen. (Report claims to be the only home caring for the cardiac adolescent boy, however Burke reserves fifteen beds for the use of cardiac boys of fifteen and sixteen, and Nichols Cottage with six beds takes boys from ten to sixteen, sometimes using in addition a bed fitted up in the barn of Reed Farm for a large adolescent boy.

[14] James A. Moore Memorial Home: The policy has been primarily to limit ages from sixteen to forty (preferably professional workers) but an occasional girl of fourteen has been accepted from time to time. "These latter have not been sufficiently numerous, however, to allow a definite division in the total beds available."

[15] New York Orthopedic Hospital, Country Branch: Expects to build an addition during 1923 to allow provision for forty beds for adults. During 1922 there were four older patients ranging from sixteen to twenty years of age who occupied four of the hospital's twenty-six beds kept in reserve.

[16] Noyes Memorial Home: To be opened in fall of 1923. Former capacity twenty. Age limits same as St. Mary's Hospital. Future capacity undetermined.

[17] St. Andrew's Convalescent Hospital, having a capacity of thirty-two beds in the winter, has only eighteen beds at the Rest from May 16th to October 1st, thus making an average of 26.5 for the year. During 1922, the Home cared for four or five children under fourteen but their policy now is to confine themselves to the care of women of refined classes with a possible age limit of sixty years.

[18] Sunnyside Farm: Seventeen beds were available up to April 1, 1923, the time of completion of a new memorial building providing forty beds, which is to be kept open the year round if demand warrants.

[19] Valeria Home: Opened for use in summer of 1923. Provides for the care of approximately fifty guests in the cottage group for men, women and married couples. If experience warrants the continuance, the Valeria Home Summer Camp, with its provision for thirty-two guests, will be utilized to take care of the summer overflow from the main institution. The present tentative plan is to set age limit of sixteen to forty-five years.

FIG. 1.—Map indicating the location of convalescent homes.

UTILIZATION OF EXISTING FACILITIES

The combined institutions with facilities for convalescence, of which forty-five are open all year round, can give approximately one million patient days of service. Allowing ten per cent. for losses in time caused by renovations, temporary shutdowns, and intervals between the discharge of old and admission of new patients, the actual available or effective capacity of these homes was about 875,000 days in 1921. The aggregate number of patient days' care rendered was slightly over 626,000, or seventy-two per cent. of the effective capacity.

An attempt was made to gauge the extent of utilization of convalescent homes by classes of patients, but the lack of available medical statistics made this impossible in any detail. As far as the data go, the highest utilization is found in the case of orthopedic and cardiac children, babies and recent maternity cases. Women utilize convalescent homes to a larger extent than men.

The extent of utilization varies in different institutions and is subject to seasonal fluctuations; it is at the lowest ebb during the months of early autumn. The underutilization of the convalescent homes does not mean that we suffer from a plethora of facilities, but rather indicates a lack of coordination. There is no central office where information as to available facilities is registered daily and where all those concerned with the sick can readily obtain such information. At the present time, each hospital has a certain select group of institutions to which it refers its patients, but it is almost impossible for the individual social worker to keep in touch with all the institutions continuously as regards vacancies.

The maladjustment of the supply of facilities to the existing demand is another contributory cause to the underutilization of the convalescent homes. Many of the patients who need convalescent care and are unable to obtain it because of the nature of their illness, could in all probability be accommodated if there were a better understanding of the existing needs and a common desire to meet these needs irrespective of whether or not it is convenient to the individual institution. It seems wasteful to add further to our facilities until the existing accommodations have been made more elastic and better adapted to the demands for service.

A lack of synchronization of effort on the part of the placement agencies with the time of discharge of the patient from the hospital is another reason for underutilization. Frequently patients cannot be accommodated in institutions at the time they leave the hospital because no plan has been made for them until they are ready to be discharged, and it is difficult to get them to go to a convalescent institution after they have been home for a certain time. Some patients are altogether unwilling to go to institutions for convalescent care because of pressing domestic or economic reasons. Women who have children to take care of in their homes, or men who have families to support, are anxious to return to work as soon as possible, and refuse convalescent care.

The admission procedures in some instances are a deterring influence. Some of the homes do not admit patients on the diagnosis of the referring physician or hospital but insist that the patient apply to the institution in person for examination with a chance of being refused admission. Other institutions do not accept the social investigations made by the referring agency and send their own agents to ascertain the financial and home conditions of the applicants.

Then there is always the individual equation of the patient with his own likes and dislikes. Some institutions enjoy a very good reputation among the patients and others are not attractive to them.

It is apparent from the findings of the survey that there is a great social waste going on in connection with the underutilization of the convalescent homes, due chiefly to a lack of a common directing policy and of generally recognized medical and administrative standards.

ADMINISTRATION.

The annual expenditure for convalescent homes serving New York City amounts to approximately two million dollars. No exact figure can be given because in many instances there are no available financial reports such as are published by hospitals. Furthermore, in the case of certain institutions, the cost is borne entirely by an individual or group of individuals who do not care to disclose the extent of their philanthropy. The figure of two million dollars for the maintenance of all the convalescent homes is a mere approximation based on incomplete data.

On the basis of possible days of care which the institution can render, the per capita per diem cost is in the neighborhood of $2.00. The Burke Foundation reports an actual per capita cost of $1.97 and the New York Orthopedic Hospital $1.96 per patient in its country branch. The daily cost at St. Andrew's Convalescent Home is reported as $1.92. The Society of the New York Hospital reports that the daily cost per patient in its convalescent cottages is $1.73.

It may be of interest that in a group of thirty-one institutions with a total annual expenditure of $817,530, 34.9 per cent. was spent on salaries and wages and 27.8 per cent. on food. This distribution of items, when compared with a similar classification of hospital expenditures, indicates that the convalescent homes spend only a somewhat smaller proportion of their revenues for salaries and wages and about the same proportion for food. The other items of expenditure could not be properly segregated for comparative purposes.

The receipts from patients do not constitute a large proportion of the total revenue. The charges in the majority of the institutions are low. In some no definite rates are charged, but the patients are asked to contribute as much as they feel they can afford. Eight of the homes are primarily for pay patients, and only two homes make a charge for care and maintenance at all commensurate with the cost. The Burke Foundation is one of those which makes no charge to its patients, this being a provision in the will of the founder of the institution.

Many of the homes maintain farms or truck gardens where produce is raised for consumption in the institutions. The gardens are considered an advantage from the economic as well as the therapeutic point of view, because some patients are allowed to engage in the occupations incident to farming and gardening.

The buildings of many of the smaller convalescent homes were built for residences and later adapted to their present use. In the case of the larger institutions the structures were specifically designed for the purpose. The arrangement of accommodation generally followed is to provide wards for children and single or double rooms for adults. Some of the homes have sleeping porches and tents in the summer. Only one institution has a resident physician. All others have some arrangement with physicians residing nearby for either regular visits or calls as needed. All but two of the institutions have nursing personnels. Two institutions for children provide dental care for their patients.

There are no generally accepted standards of medical and nursing care for the various types of patients nor a scientifically formulated regimen of life. Curative workshops have not been generally introduced, nor is the value of occupation therapy admitted by all of the homes. In some institutions, it is part and parcel of the daily program, while in others it is considered a hindrance to convalescence. In some of the larger institutions mothers are taught how to care for and prepare food for their babies and the general care of infants. In most institutions, there are facilities for recreation, but neither recreation nor exercise have been developed in accordance with standards based on an accurate knowledge of therapeutic results for the several types of patients. Experimentation along these lines is being carried on at the Burke Foundation and the Mineola Home, where supervised work and games of various kinds are encouraged for cardiacs and other patients. Several of the institutions for children have teachers or kindergartners and also play directors.

Considering the tremendous opportunity of the convalescent homes to restore large numbers of patients to normal ways of life and economic usefulness, it seems imperative that a joint effort on the part of the institutions should be made to secure data which will serve as a foundation for a rational and effective development of the work in its administrative as well as its professional branches.

HOSPITAL EXPERIENCE.

In order to obtain a cross section view of the mechanism by which hospital patients are transferred to convalescent homes, a study was made of a group of records of patients selected at random in the social service departments of twenty-five hospitals. Altogether 3,236 records were read, which dated far enough back to include a complete history of convalescence. The cases studied covered dispensary cases as well as distinctly hospital cases.

Of the 3,236 cases, 980 or 30.3 per cent., were certified by the social service departments as needing institutional convalescent care. This need was determined by medical reasons in some of the institutions, on account of home conditions in others, and in some instances a combination of both was the basis. The study disclosed a marked variation from hospital to hospital with regard to the certification of patients as needing institutional convalescent care, indicating a lack of a generally accepted standard of selection. In some of the children's services, the variations ranged from eighteen per cent. to seventy-two per cent., and in the case of adults the variations were less marked although considerable.

It was surprising to find that the convalescent need was met in 81.8 per cent. of the cases. Here again, the several hospitals varied greatly in their ability to place patients; hospitals having their own country branches were of course one hundred per cent. successful. It is of interest that in the group of patients studied, convalescence was provided to the extent of 85.7 per cent. in the case of adult males, 81.2 per cent. in the case of children, and eighty per cent. in the case of adult females. The study further showed that the hospitals most successful in placing their patients were those in which the need was ascertained several days before the discharge of the patient. Of the 802 patients whose convalescent need was filled, thirty-two per cent. were placed in convalescent institutions on the day of discharge, 12.6 per cent. within three days afterward, thirteen per cent. within a week, and thirty-two per cent. were not placed for a week following discharge from the hospital, and for 10.4 per cent. there was no information on the records as to the date when they were placed in convalescent homes.

An effort was made to correlate the length of stay of patients in the hospitals with that in the convalescent homes, but as the length of stay in the convalescent homes was not given on the social service records in a large number of cases, the correlation could not be worked out. An analysis of the failures to secure the necessary convalescent care showed that the largest number was in the group of adult females, primarily because of their refusal to go to the convalescent homes on account of home responsibility. According to the medical classification, the greatest number of failures was among surgical cases, and also among neurological and orthopedic cases.

In 57.2 per cent. of the social service records of the patients certified as in need of convalescent care, there was no entry with regard to followup service; twenty-seven per cent. were followed up within two weeks after their discharge from the hospital, and fifteen per cent. in a period of three weeks to three months.

The study of records revealed a lack of any uniformity of approach to the problem of convalescence by the hospitals. There seems to be a need of a better formulation on the part of the hospital authorities of the types of patients which should be urged to take institutional care and under what conditions it should be carried out, and of a better timing of the discharge from the hospital with admission to a convalescent home.

SUMMARY.

Institutional convalescent care has evidently become recognized as a community responsibility in New York City. According to an estimate made by Dr. Brush in the April 15, 1923, issue of the Nation's Health, New York City maintains about fifty per cent, of all the convalescent homes in the country. The investment in these homes reaches many millions and the aggregate cost of maintenance amounts to a considerable sum annually. Some of the institutions have large endowments, notably the Burke Foundation, the Solomon and Betty Loeb Memorial and the Valeria Home, which is in the process of construction and which is to serve the need of the middle class. The outstanding need at the present time is a community policy with reference to institutional convalescence, a coordination of all the existing activities as well as a formulation of adequate administrative and medical standards. Until such standards are formulated and adhered to, many physicians and surgeons would hesitate to curtail the length of hospital stay of patients and to transfer them to convalescent homes. A central bureau of information or registry could be made very serviceable in promoting higher standards and in reducing the amount of underutilization of existing facilities.

Historical Medicine

Egypt and Persia in the Days of Herodotus and Medical Problems Today

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

Murray or Mahaffy, or perhaps it was some other one of those numerous British cousins of ours who have brought about the present revival of tolerance if not of interest in the classics, has laughed over the joke Herodotus tells on Hecatæus. Herodotus marvelled at the high antiquity of the Egyptians and, it must be confessed, was often somewhat taken in by their priests. Hecatæus had been to Egypt before him and it seems had been airing his snobbery in his pride of ancient lineage before the priests of Zeus, as Herodotus called them. He prided himself on his genealogy and boasted he could trace his origin back through sixteen generations to some god. The priests took him into a big room filled with wooden images of archpriests, noblemen, descended in a straight line for three hundred and forty-five generations and not the most remote could claim a god as his sire. Herodotus evidently chuckled over this for he remarks: "Such the priests showed me likewise, but I said nothing about my lineage" (1). As for ourselves, we are inclined to think both the Greek and the priests of the Nile were lying, but we may in this instance remark the tact of Herodotus as perhaps an example of the way he insinuated himself into the good graces of the priests. He must have done it all the more easily from being himself a pious man, not disposed to scoff at holy things, one too disposed to take seriously from scientific evidence the claim of the priests that Egypt and the Egyptians, not necessarily the wood in their statues, had endured already, some ten thousand years. At least, when Herodotus went to Egypt, the barriers that usually prevent the inquisitive traveler from penetrating into the innermost arcana of the civilization of less remote times under the rule of hierarchies and monarchies must have been let down for him. He seems at once to have got to the heart of it, to Sais and Heliopolis, where our medical papyri indicate to us was the fountain of learning and medical science. It may be doubted whether he got so familiar with the priests there that he could joke with them about their genealogy, their religion or their science, but he joked about them and came as near, on occasions, to scoffing at them as was possible for a sincerely pious man, though they did fill him with some stories we even yet refuse to believe after all the confirmation we have received from the archeologists in recent years. There is no doubt the priests of the Nile had lying and pretense reduced to a fine art when the Greeks first began to see the sights in the marvelous land of the Pharaohs, but modern archeology has reduced the number of apparent lies Herodotus in his gullibility has transmitted to us. The opening sentence of the *Papyrus Ebers,* filled with some of the medical lore of Egypt a thousand years before Herodotus travelled to see the sights there, spoke in its own name as though sheltered in the Holy of Holies, medicine cringing behind the robe of religion: "I come out of Heliopolis with the priests of het-āāt, Lords of Defense, Kings of Eternity and Salvation. I am come out of Sais with the mother madonnas who protect me" (11). These as Herodotus got it into his head, from what the priest told him, twisting Egyptian mythology into Greek beliefs, were sprung from Demeter, the mother of the gods, and Dionysius, (2) the wine god son of Zeus. As to the Heliopolitans who thus protected medicine, he says (3) they were the most learned of the Egyptians. In Sais too was safety to be found, the most fertile of grain lands, not far off in lower Egypt.

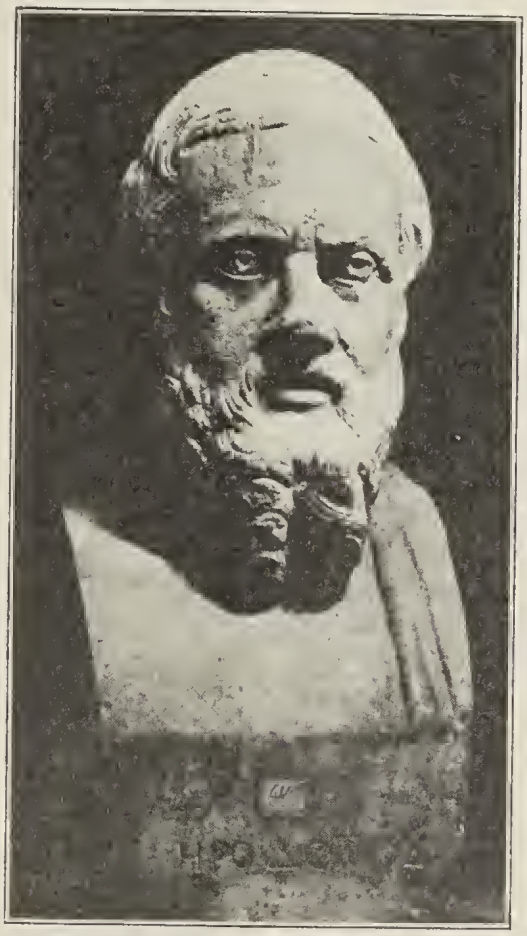

FIG. 1.—Statue of Herodotus. (From Greek and Roman portraits by Dr. Anton Hekler.)

In these columns I have quoted (12) from the *IV, Maladies of Hippocrates* and incidentally I have referred to some indications of the affiliation of this with the medicine we get in the Ebers and other papyri. The most prominent factor in the etiology of disease is said to be plethora—from errors of diet and regimen. There are others, of course, but this the author mentions and emphasizes. Now listen to Herodotus: "Those who live on the grain sown soil of Egypt are by far the most learned men in the history of mankind of any I have ever met. Their manner of life is such that they purge themselves by emetics and laxatives three days in the month, seeking health for themselves with clysters also, believing that diseases come from the injection of food" (4). Not only is their theory and practise here conformable to that of the Hippocratic book, but the detail of a three day purge finds a parallel in the three day period of the humoral doctrine of this book. "A cycle of three days presides over nutrition," is the summary Littrè gives of paragraph 42 in the *IV Maladies of Hippocrates.* This

practice was sound. Their therapy had a physiological basis in its periodical attempt to empty the gallbladder of those dwelling in the fierce heat of the sands along the Nile.

We get a glimpse in Herodotus (5) how the idea of the bile as the seat of the primary factors of disease etiology dwelt in the medical minds of his day, for he but echoes it. Near the Mæotian Marsh, the modern Sea of Azov branching off from the Black Sea south of what was once Russia, from which flows the River Don, the ancient Tanais, toward the Caspian Sea—along the Tanais was, according to Herodotus, a stretch of rich grazing country. Against the Scythians dwelling there Darius rashly led a Persian expedition: "Along these rivers I have named the Scythians get something for themselves and the grass which grows there for their cattle is the best bile producing in Scythia of all I have seen. In these cattle when opened it can be measured by the scales that thus it is." I confess I have given my own translation of this passage, in preference to that of Rawlinson or to that of Cary, but only in inserting the literal meaning of the words which exist there and make the passage significant to us on the scent of bile fads in the time of Herodotus have I ventured to differ from these laymen. It makes it quite apparent that the bile had its importance for an historian of Herodotus's catholicity which it would not have had except for the aura of medical theory which surrounded it. "How is your liver?" used to be a stage joke greeting the British exile when he returned from India. Though it was the appendix that was in the centre of the field even as a lay interest a generation ago, we have returned surgically to the gallbladder. "Thou art the joy of my liver," the Arab still exclaims, and for the Babylonian of old it held the mysteries of life, and from Babylon we imagine that part of the humoral doctrine received the extreme prominence quite evident in the etiology and pathology of Hippocrates. Grass and cattle, rich in bile, then, was a matter of interest to the commonality of readers in the day of Herodotus, though the turn of the phrase seems a little strange to us today, busy with another form of the same fad. The bile and the blood sera are coming into their own again. In the marshes of the delta of the Nile and in the Mæotian, where the grass grew rank for the cattle, it behooved men to keep the bile moving, to keep their bowels open and their faith in their gods for the rest of it.

There has been some discussion of late years as to the origin of wheat. It has not been very satisfactory either from an historical or a biological point of view. The weight of opinion seems to be that it originated, but it is better to say it was first used, as a food growing wild in the region of the isthmus of Suez, because in that region were preserved the most ancient records we have in archeology, very far back in Egyptian civilization, not long after the first of those images should have been made which the priests of Zeus showed Hecatæus and Herodotus. But there are a number of grains possible, if not very suitable for food, spoken of in early historical records by the nomenclature of which it is difficult to identify them with our modern wheat of commerce. There is an even larger number of varieties of this today. We can not always be sure the records on stone or in the papyri, despite our dictionaries, are really referring to the plant which now forms the staple cereal food of western civilization. Certain it is that no such preponderance as it now and with us presents existed in the days of Herodotus in Egypt or elsewhere.

In his day he said (6) that other peoples lived from wheat and barley, hidebound provincialists thinking their own way of living was the only way of living, but the Egyptians expressed the greatest contempt for any one using such stuff. They made their bread from rye or spelt (?), if this is the proper rendering, for Herodotus uses another term, "zeia." This word we have, with a twist, manufactured into the scientific term for our corn in America. The reader takes note, however, that the Greek words for the food of the Egyptians corresponded to that of the fodder the Greeks fed to horses. Despite the confusion one is reminded of that narrow-minded Colossus of learning who insisted in his dictionary that oats was a food for horses in England and for men in Scotland. On that subject then, the subject of intolerance most pronounced that man exhibits toward his fellow man, man's daily food, we find the Egyptians gibing at the Greeks and the latter countering with the Scotch rejoinder to Dr. Johnson: "Where do you find such horses and where such men?" Greece boasted of her men and the cattle of the Egyptian Delta were the finest in the world. The practical point for us here, however, is: "If it was rye that was the staple bread of Egypt when she was furnishing Greece with medical theories, is it any wonder, getting back to our humoral doctrine in the *IV Maladies of Hippocrates,* is it any wonder the cause of disease was the food? Our rye bread gives our western constitutions many a tussle with the belly ache. Any constitution which could flourish under the régime of the maza cake of the Mediterranean peoples in the time of Hippocrates differed from ours, but then man does differ from his fellow man, and the rye and barley husks and the stone grit Egyptologists find in the more cheaply embalmed mummies may have been good for them in life. We need not be too sure the Mediterranean people would have had less belly ache on finely sifted wheat flour. History after all lends no more support than comedy to the modern dietitian, who is so honest about his calories that he keeps scales on his breakfast table for his children's starches and proteins. Molière's imaginary sick man asks, scrupulous to follow his doctor's directions: "Doctor, if you please, how many grains of salt shall I put on this egg?"

Nevertheless, even if one man's food is another man's poison, one man's sufficiency another man's plethora, we may well believe purging was a relief as a sanitary measure. Despite the frills of ancient and modern dietitians man's digestive apparatus, as it has evolved since the days of the cave, may be considered the most wonderfully adapted biological structure familiar to modern science, and for mere man himself to seek to gauge it down to averages is absurd. If any considerable number of the race clustered around averages instead of being scattered along a line extending from one pole to another, and from the childhood of the Nile to the artificial life of our modern cities, man would have perished from the earth. A man's belly refuses to take much interest in averages or calories. Every belly is a law to itself, but it does need emptying.

How much the Persians brought to the land of Egypt besides a masterful organization of the political and hierarchical and educational bureaucracies, fallen into feebleness and decay, can not be told from Herodotus's pages altogether, but from other sources we can fill out the hints he gives us. It is plainer from him, however, that they furthered and increased the traffic in merchandise and ideas which had existed long before the Persian hegemony between the Nile and the Indus. On the establishment of this we can well believe some sanitary ideas came over the land routes as well as across the Red Sea to Western lands. The Persians themselves had a high notion of antisepsis, doubtless derived from their experience with tropical infections. Asepsis was a widespread ritual of many of the ancient rituals, but especially of the Persian. The sanitary code of their religious theory and practice can easily be traced in their epics. Their ethical precepts were derived from their religion. It is said the Persian boy was taught to ride a horse and shoot the bow and speak the truth. Herodotus says (1) they were taught to pay their debts and speak the truth. In these respects doubtless they had much to teach the Greeks, but the Persian was also taught a broader catholicity of sympathy. Not for him alone who in private was making his oblations and offerings did prayers ascend to the gods, but for all Persians and the king was the aid of Heaven sought (8). The Greek concocted a tale complimenting himself for the skill he showed in cheating the gods by taking to himself the thighs of victims to eat at the sacrifice and offering up the entrails to divinity, rib roast for him and tripe for God.

The Greek prayed for himself alone, the Persian for all mankind, as may be seen also in the Zend Avesta. Such were the Persians in ethics and in religion. As to sanitation Herodotus relates (9) that Cyrus carried with him on his Babylon campaign the water of the Choaspes, which ran through Susa, for his drink—and boiled. If Alexander had done that when he captured Babylon the world would have been different. For the Persians the cosmic elements were a part of the holiness of God. To defile them with the dead human body or to touch the dead body, except with certain precautions, was a mortal sin. "In the rivers," says Herodotus, "they neither pissed nor spit nor washed their hands nor allowed anyone else to do so" (7). Lepers they expelled from their territory. Babylon had a dawning conception of contagion and the Jews evidently shared it. The leper was unclean, impossible for purification and liable to contaminate all living things he touched. This idea of contagion together with the hatred of race was at the bottom of caste feeling in India. The conquered were not only hated and despised, but contagion raged among them in their misery. With an eye to our own danger we try to stamp out typhus among our enemies today. Altruism, the love for our fellowmen, an anchor cast out to windward with it all, advances hand in hand with sanitation.

Dead bodies were not allowed in Persia to pollute the earth either, much less, as in the Nile, to float in the current of the Choaspes. Its waters for Cyrus to drink were put in silver vessels and they were boiled. If Headlam (13) is correct in his interpretation of a line in Æschylus it was known to the Greeks of his day. Commenting on the news of Salamis the messenger brings to Susa, the poet makes the Chorus speak of bodies soaking in the sea and dashed against the rocks of the Ægean shores after the naval battle,—"they are torn by the dumb children of the *One* none should pollute," that is, the sea dogs of Greece, the sons of Poseidon, have left the Persian corpses to float in the water, rising and falling with the tide and polluting the element held sacred by the Persians. Twenty-five hundred years ago the Persians were further along on the road of sanitation than we were seventy-five years ago. In that period, as a matter of fact in less than two generations of men, by our triumphant study of infection, which we so plainly see the Persians entering on before their civilization had ended its short career, we have erected the beneficent fabric of sanitation which the best of our race are trying to extend to lands over which the Persians ruled all but 3,000 years ago, to lengthen the span of life of the men who now dwell there. But we have chanted our triumphs enough and I am going to turn to an aspect of the question of average longevity which has not received proportionate recognition.

FIG. 6.—The miller. (From Maspero's *Egypte*, a volume of the *Histoire Generale de l'Art*, 1912.)

We seem in civilized countries to have lengthened the average span of life, but statisticians say it has been done by keeping sickly infants alive until well up in middle life and that when a man has passed fifty he has a poorer chance of living until he is a hundred than he would have had a hundred years ago. By the time this essay sees the light I may have had something (15) to say of the ethnological aspects of euthanasia and something also of its social implications, but not of the special point of view from which the medical man views its ethical aspect. By our code, by the general sentiment of laymen, by the enactment of law, all of which are the outgrowth of historical tradition, we accept the central doctrine for us, that it is the duty of the doctor to keep the breath of life in his patient as long as possible. He has nothing to do with hope or despair, his duty is to prolong the life of the individual man regardless of his miseries in the past and disregarding the certainty of his sufferings in the future if he survives. The historical review of the question in its political and social aspects, besides the rather meagre gleanings we get from medical history, is sufficient to convince us of the unwisdom of placing in hands, other than those of the judiciary of the state, the function of deciding when a man has lived long enough. The reprehensibility of making this a medical question at all, I think, has been accepted in all ages since Hippocrates by the vast majority of conscientious practitioners of medicine. The instances to be found in Herodotus, as among the Massageate (10) who killed Cyrus and smoked cannabis indica, and in modern writers, where it is tribal custom for children and relations to kill the sick or aged in order to save them from further suffering, are all or nearly all culled from accounts of men in a very primitive state of culture. That practice has not stood the test of the experience of mankind, but that the knowledge of the experience gained by it in the history of man's past has slipped from the intelligence of the vast majority of men is not only astonishing but deplorable.

Certain strata of human intelligence stood aghast at Osler's playful suggestion that at sixty men should be chloroformed. This jest was such a novelty to them, so ghastly, so weird, with such a kernel of wisdom deep down in it, that his own life was made miserable by this unfortunate casual slip of a joke. He miscalculated the stage of culture of the men among whom he lived. They had forgotten their past. He wanted to raise the flicker of a smile by reminding men of a former sorry experience and he raised a tornado. The grim fact which was meant to elicit a grim smile that needed no comment did not dwell in the consciousness of supposedly intelligent men. This mistake in judging of the historical perspective of the men of his time was particularly mortifying to a man of his tactful personality, who felt himself, as in truth he was for the main part, in touch with the sympathies and thoughts of his fellow men. Those who knew him best may perhaps be able to trace a strengthening of his conviction of the utility to medical men of a knowledge of history, especially of medical history, to this episode.

The suggestion was a statute not a joke among the Ceians, according to Strabo (14), a fact and not a pleasantry among many tribes of primitive men; and recent travelers have told us we need not go back to Herodotus or Diodorus Siculus to find the practice in force. Not only does it emerge from ancient history but from modern ethnography as well. The Ceians, in an emergency it is true, made all over sixty drink hemlock, but we may be sure no English-speaking doctor will joke on this matter in relation to modern conditions until Osler's unfortunate venture is forgotten.

Yet there still remain some sober observations, which may be made by those not so famous as Osler, or so well loved, without drawing the fire of the public, but it is necessary, it seems, to refer to the fact, as I have done here, that the question of euthanasia is an old one and hedged by many social and political considerations in the history of the past. It is a burning personal question, too, at the back of many a man's mind. Read the *Life of Elie Metchnikoff*, wonderfully well written by his wife. It will then be seen the real problem which confronts us is not to live long but to die comfortably, and primitive man was striking right at the heart of it when he put his aged and sick to death. To lengthen the span of life is a sensible goal for modern medical science only when it holds fast firmly to the determination to abolish its asperities so far as they depend on the sufferings of disease, especially that of old age. A man may suffer when young with the prospect of enjoying the future, but there is nothing for it but the hemlock or the chloroform when a man is past sixty. To render old age palatable is very much more important than to lengthen it. If we are not going to engage seriously in that effort I see no reason we should not adopt the motto of a short life and a merry one. Why prolong life simply?

Life is not a question simply of statistics, it is a question of euthanasia. Life eludes statistics. On the face of the facts presented by living beings, the enormous variations in its phenomena, especially those of the human race, statistics are not a basis on which to build theories, except false ones, which have their value, however; they are adjuvants only to theories of any kind. They are of value chiefly when they deal with more or less homogeneous phenomena. For the individual man's diet and régimen they have small value. For reasons which I have alluded to also the medical man has perhaps no more right by his negligence to shorten the life of men in general than of a patient in particular, but there is no social or political reason why he should not put emphasis rather upon a comfortable death than a long life, especially in view of the fact that they are not necessarily antagonistic, indeed quite the contrary.

Herodotus tells us, at the dawn of history, a tale of the Massagetæ, which reveals to us how primitive men in his day were face to face with the problem, and elsewhere he lets us see that men, not primitive at all, were turning over in their minds this part of the problems of life and death, as well as we. The Massagetæ were not mere savages either. Cyrus rashly crossed the Araxes and burst in upon them and ended his own life, sword in hand, comfortably compared to Metchnikoff, for Metchnikoff, who labored so heroically to lengthen the span of man's life, twice in the course of his own attempted suicide and died a miserable death at last.

Health may be something which, as has been said by sententious and successful health officials, can be bought. Whether old age is something that can be bought is an entirely different question. The question first to be solved, which the Massagetæ solved in a way we shrink from and Osler joked about, is whether old age is worth the price. The matter of lengthening the *average* span of life has nothing to do with the longevity of the old, or very little to do with it and as little with the question of making it worth while. I will leave other gentlemen who have passed sixty to argue how valuable our services are to the State. I have my doubts about that, as did Osler, but emulating the prudence of Herodotus in suppressing the account of his genealogy, I shall say nothing about it. The longevity of a man I fear has more to do with his genealogy than the environment the health boards can buy for us.

Long life is more a matter of heredity than environment, and when the eugenists have settled just what kind of a man they are going to breed perhaps they will include this as a point to incorporate in his inheritance. If they do, I do not know how they are going to settle it with the health boards if they try to buy longevity as well as health. Sickly children who have had health bought for them until they have come to maturity are apt to leave descendants for whom it will have to be bought, too, and after a while the cost will be ruinous. Who can tell but a wiser generation will revert not only to the ways of Massagetæ and take seriously Osler's joke, but like the Spartans will throw sickly children into the duck ponds? Those at present beyond sixty can at least sincerely congratulate themselves they will not be called on to decide between the eugenists and the health boards.

Elizabeth Fry, Pastor Fliedner, and Florence Nightingale.—Dr. Henry Barton Jacobs (*Annals of Medical History,* March, 1921), says that the work of Elizabeth Fry in bettering the lot of prisoners, the insane and the poor, and that of Florence Nightingale in the field of nursing are well known throughout the world, but the place of Theodore Fliedner, called pastor, who was a connecting bond between the two women, has not been so widely recognized, even by the medical profession.

Fliedner, born in 1800, was the son of a Lutheran clergyman of very limited means, and worked his way through the universities of Giessen and Göttingen by sawing wood, blacking boots and tutoring. While acting as tutor to a clergyman's family in Cologne, he sometimes assisted his employer in his parish and prison work, and in this way gained an insight into the hardships and evils of the lives of discharged prisoners, especially women. A little later he was made pastor of a church in a little village, Kaiserswerth, on the Rhine near Düsseldorf. He had hardly taken up his abode here when the velvet mill, which gave employment to most of the villagers, was burned and the people thrown out of work, resulting in their inability to supply money for the support of the parish. Rather than seek a position elsewhere, Fliedner stuck by his congregation and made a tour of several of the European countries in a successful attempt to raise funds to maintain his church. While in England he met Elizabeth Fry and was greatly impressed by her work at Newgate Prison. He returned to his little village inspired with zeal to better the lot of prisoners in his own country. He began his work in the Düsseldorf prison and founded the first German society of improving prison discipline. His greatest problem was the protection of discharged women prisoners, whom the social conditions of the times condemned to one possible source of livelihood—a life on the streets. He and his wife decided to begin the solution of this problem by opening their home as a refuge to discharged women prisoners. The first applicant speedily appeared. This was the first of the Kaiserswerth institutions, afterwards famous throughout Europe. During the winter nine more women sought refuge with the pastor, and a separate building was built for them. Some of these women had children, and the next step was to provide for them. An infant school, resembling somewhat the modern kindergarten, was established, and a little later, a school for the training of the nurse-teachers, who were also to work among the poor and sick in the community. So, in 1836, the Deaconess Hospital Kaiserswerth was opened without patients and without deaconesses, but "with faith abundant." A few days after the opening, the first patient, a servant girl, applied for admission, and soon sixty patients were under treatment. Fliedner's wife was the organizer and administrator of this school of nursing.

When Elizabeth Fry visited Germany, she was much impressed with the work being done at Kaiserswerth, and upon her return to England was instrumental in founding the nursing sisters. Florence Nightingale spent a fortnight at Kaiserswerth and was so enthusiastic over the pastor's work that she returned later to take the course in nursing given at his hospital.

Editorial Articles

PUBLIC EDUCATION IN MEDICAL MATTERS

The public has long been educated on public health matters, in fact, so thoroughly that widespread epidemics in civilized countries are unknown. This result would have been impossible without the cooperation of the general public. Domestic hygiene, too, is a question which is beginning to be more thoroughly understood by the masses, who now demand well built and properly ventilated houses. Infant welfare and the care and rearing of the child are other matters to which attention is paid nowadays.

All these questions, however, are comprehensible, to some extent, at least, to the man in the street. It is the chronic diseases and their treatment, preventive or otherwise, which puzzle the layman. But it is to the interest of everybody that the community at large shall be made acquainted with the symptoms of certain diseases, in order that they may be prevented. Cancer, for instance, can be treated successfully in its early stages, but the public should know what the premonitory symptoms are. In this country and in Canada these subjects are taught by propaganda, crude in many respects, possibly, but on the whole fairly effective. The advance of tuberculosis also has been stayed, partly by means of a more or less judicious public propaganda.

One of the most recent spheres of activity in preventive medicine is that of mental hygiene. Conceptions of mental disorder have changed greatly. It is now recognized that, if treated intelligently during the early stages, many cases of mental aberration can be prevented from proceeding further. It is also becoming a matter of common knowledge that mental disorders sometimes proceed from physical causes, or that physical causes are prominent factors in their development; that if these are treated successfully, recovery of physical and mental health will follow.

In the *Lancet* for October 20th is an article by Dr. J. G. Porter Phillips on the early treatment of mental disorders, in which he advocates the education of the public with regard to certain salient points. After stating that the secret of modern progress often lies in propaganda, he draws attention to the fact that in the United States and Canada much has been done to educate the public and to enlighten them as to the best means of facing the problems of early mental disorders. While lamenting that in Great Britain intensive propaganda is never likely to be carried to the extent to which it is carried here, he holds that there is no reason why an organized propaganda in Great Britain should not attempt to arouse the public conscience to its obvious duty in the matter of early mental disorder in the adult and defective mentality in the child. It should, in his opinion, be the duty of every psychiatrist to educate the minds, not only of patients and their relatives, but also those of members of the medical profession, to accept the fact that mental disorder is a common everyday illness, with which no stigma or sinister atmosphere should be associated.

Dr. Phillips also emphasized another sphere of activity greatly more in evidence in this country than in Great Britain, which is that attached to all mental out patient clinics will be found the highly trained psychiatric social worker. No doubt with this end in view, namely, that of better social organization, a National Council of Mental Hygiene has been inaugurated in England, to which body there have been elected to its executive committee men and women who from their training and experience are well qualified to undertake the intricate and onerous task of social readjustment in so far as it concerns the mentally unstable.

The education of the public is proceeding satisfactorily as to some phases of medicine and surgery. With respect to research work the general public is profoundly ignorant of its value and do not understand that although immediate results are not seen, it is essential to the successful prosecution of a campaign waged against disease. Fortunately, in this country, rich men are thoroughly cognizant of its importance and have given money prodigally to forward medical research work.

Before leaving the subject of educating the public on medical matters, it may not be amiss to say that medical men sometimes are in need of education. It is freely admitted that in the fight against disease a factor of the first importance is early recognition of the underlying cause. If a correct early diagnosis is made, grave results may be prevented. In the diagnosis of cancer the disease can often be detected in its early stages only by one experienced in its manifestations. Therefore, if a medical man is uncertain as to the diagnosis, a specialist should be called in. However, in country districts and when the patient is poor this course is generally out of the question, and medical men everywhere should be made conversant as far as possible with the early symptoms of disease. In this way alone, and by the education of the public, can treatment be rendered less empirical.

INFECTIONS OF THE RESPIRATORY TRACT

The *Monthly Bulletin* of the Boston Health Department for September prints an admirable unsigned article on acute infections of the respiratory tract, under the title A Serious Health Problem. In the cities and larger towns of this part of the country deaths and disability among persons in the productive period of life, incident upon such infections, the article states, constitute the most serious health problem that confronts us. Yet the prevention of deaths and disability from this source at present receives the least attention of any of our health problems. "The deaths, expense, and absence from productive occupations which are going to occur in Boston the next eight months from 'colds' and their resulting complications of infections of ears, sinuses, tonsils, lungs and other organs, will mean a greater relative economic loss to Boston than any tropical city in which yellow fever was endemic ever suffered from that disease. The yellow fever never killed the natives of such a city as colds kill us." The same might well be said of New York, though perhaps not in so extreme a degree, since the New York climate is milder and dryer than that of Boston. However, respiratory infections do cause a large proportion of our winter diseases, so we can listen with profit to these words of warning from Boston.

It is suggested that families adopt the practice in the home of boiling or sterilizing the family eating and drinking utensils after they have been used, instead of following the usual practice of "slushing" them about in the lukewarm water furnished since the war by most apartment houses, and that this be carried out as a regular routine procedure, and not left to be adopted until after some member of the family falls sick. To produce infection, something is usually needed besides the pathogenic organism. A lowered degree of natural resistance must ordinarily be present, and anything that tends to put the mucous membrane of the nose, throat or lungs in an abnormal condition tends to do this. Protein material in the atmosphere, irritating dusts, alkalies, a steamheated, dried out atmosphere, all these are agencies for harm. A steamheated habitation should have a degree of relative humidity comparable with that to be found out of doors on a cold day. Hardly do we ever find such conditions in houses and apartments of today. "Yet this might just as easily be done as in establishments where the artificial maintenance of a certain degree of relative humidity is necessary for manufacturing purposes."

People should be taught that, when they find themselves infected, the chances of serious complications may be lessened by applying to themselves the treatment that is efficacious in helping the body to overcome surgical infections, that is, rest in bed, especially when the temperature is abnormal. It means also rest of the infected part. "Violent efforts to clear a congested obstructed nose often serve to drive the infective material into the eustachian tubes or sinuses. Injudicious treatment of an infected throat also may favor the extension of the infective process."

The writer believes that the only real solution of the problem will be the bringing about in the general population of some sort of artificial immunity comparable to that now available for typhoid fever. He does not approve of research or experimental work being undertaken by an official state or municipal health agency, but he does advocate doing more work of this kind with a view to demonstrating some practicable solution of this problem of acute respiratory infections. "It is certainly the duty of every municipal health department to emphasize the economic seriousness of the problem and to endeavor by every means within its power to stimulate and encourage efforts to find a practical method for its solution."

THE MECHANISM AND PHYSIOLOGY OF SEX DETERMINATION AND THE ACTION OF HORMONES

Although it has been claimed by certain members of the medical profession that sex can be determined by will, or rather by following a definite procedure, this view has been generally rejected. It is believed that sex is an accident, dependent upon the laws of chance. It is a question of no moment to the community as a whole, whether an individual is male or female, so long as the numbers are approximately equal. But to the individual it is a very grave matter, or thought to be so, and thus sex determination has ever been a problem of quite absorbing interest. A great deal of literature has appeared on the subject, some illuminating and some confusing. A book by Dr. Richard Goldschmidt has been published recently which, while it presupposes a more or less intimate knowledge of the subject, especially from its modern points of view, discusses the question on the basis of sex as a Mendelian character. The main argument of the author is summed up as follows:

Every developing individual of a bisexual organism contains the substances whose action can call forth one or the other sex. A particular mechanism disclosed by Mendelian experiment and visible in the sex chromosomes, distributes these substances to the offspring in such a manner that half the offspring receive the substances in one proportion while the rest receive them in another, so that either the male or the female substances are present in excess quantity. These substances act like enzymes, proportionately to their concentration. The quantitative difference of the substances in the two groups of individuals is automatically responsible for either the male or the female enzyme completing the determining reaction first. This reaction is the product of specific hormones of sexual differentiation.

In connection with hormones, Prof. E. H. Starling, their discoverer, in the Harveian Oration given before the Royal College of Physicians of London recently, devoted a considerable part of the address to the consideration of the therapeutics of hormones. He pointed out that the ideal method of treating disease would be to control, by promotion or suppression, the growth of the cells themselves whose function it is to form these specific hormones, and he further pointed out that the power of controlling the growth of cells involves the solution of the cancer problem. Experiments on the growth of normal cells outside the body have shown that they can be stimulated to vie with cancer cells in the rate of their growth, or can be inhibited altogether, according to the nature of the chemical substances with which they are supplied. And it is also known that the growth of certain cells, such as those of the mammary gland or the uterus, is excited by specific chemical substances produced in the ovary or fetus. In Professor Starling's opinion, we may be able to find specific substances or conditions for any tissue of the body which may excite growth when this is retarded, or diminish growth when this is in excess. There seems also to be a possible relationship between Dr. Goldschmidt's views on sex control and the development of cancer.

Miss Stye's investigations on the inheritance of cancer in mice, referred to by Prof. R. G. Wells in the *Journal of the American Medical Association*, 1923, pp. 1017, 1103, show that the tendency to develop cancer behaves as a Mendelian recessive character. Moreover, the age incidence of the disease suggests that this may be another example of the quantitative efficacy, in time, of a veritable quality such as explains the changes of sex in moths and fowls. This would be in line with Dr. Goldschmidt's theory that each factor in the determination of sex is a dose which may diminish or be exhausted in the course of the individual's life. The female characteristics of a hen, according to this conception, may wear out, and it may become not only an anatomical but a functional cock. It is only a female because its female characteristics predominate and not because it possesses no male characteristics.

However, the determination of sex, after all, is a question of no particular significance or importance, that is, so long as the sexes are fairly equally divided. Perhaps, too, it is well that it is not in the power of man to control this matter. Neither, perhaps, is it desirable that we should be able to prolong our life far beyond the allotted span. But it is important that disease, disability and pain should be controlled or prevented, or the cutting off a man or woman by disease in the prime of life, which comes about by ignorance or disregard of the immutable laws of nature, the secrets of which are being continually revealed to us by scientific investigations. It is believed by many that in the study of the ductless glands rests the hope of the physical and mental salvation or regeneration of the human race, and in a return to a less artificial mode of living, especially with regard to diet. Discoveries thus far relating to the ductless glands have been remarkable, but as yet only the fringe has been touched. Their potentialities and possibilities promise so much that they almost stagger the imagination. It may be taken as decided that there is no recipe for getting a boy or girl at will. It has been decided that excess or deficiency of specific hormones have much to do with ill health and that as far as we know that hormones are identical throughout all the classes of vertebrates. It is further known that when the active principle is stored up in the gland and unaltered by the processes of digestion, that all the curative effects of the hormone can be obtained if dried thyroid is given by the mouth. Exact knowledge as to resistant powers of the other hormones to the action of the digestive hormone is not at present full or definite. However, the day seems to be approaching when the chemical constitution of all the hormones will be revealed, and when relatively colossal doses may be given by the mouth. When the exact action of the hormone is made plain a new era in preventive, curative and remedial medicine will be inaugurated. In fact, the reign of empirical treatment will have passed away forever.

WHAT IS A POISON?

Some twenty years ago Sir Michael Foster wrote: "Everything that gets into the body, that gets into the blood and can't be made use of by the body, does harm; it acts like a poison; indeed is a poison." He added: "Too much water, like too much anything else, is a poison."

Such a broad definition of a poison has not, we fear, entered the minds of most of us, and we have been brought up to believe that, as for water, there could be no such thing as its excess ingestion. The statement of the great physiologist seems to have had little influence with us, and everyday injury from excess of pork and beans, from cakes and candy, is hardly dreamed of. Salt has been looked upon with suspicion, also some things for which there is an idiosyncrasy, but patients have been urged to drink water by the gallon, as a therapeutic measure.

Of course, commonsense must wait on laboratory experiments, but now comes Rowntree who asserts that, both in man and animals, water ingested in excess leads to water intoxication which, being interpreted, means poisoning. This intoxication ends in death unless the excess consumption be stopped. The symptoms shown point to disturbance of the nervous system, and as the nervous system is most sensitive to blood changes this is to be expected.

There are, of course, many people who would be the better for drinking more water, but when an amount is reached where there is sufficient to induce good functioning of the bowels and the movements are soft, it is not well to push the intake further, and one should always consult the person's thirst. In hot weather too much water is often taken. The sweating apparatus is swamped in trying to get rid of the excess, so that the skin is bathed in warm water rather than covered with a thinner layer of rapidly evaporating sweat. The blood becomes too dilute with excess of water and undue languor and weakness result.

It is well to keep in mind that "everything that can't be made use of by the body does harm," and that probably the most common poisoning is by the most common substances we take into our mouths.

THE FIRST INTERNATIONAL HEALTH EDUCATIONAL CONFERENCE

The first International Health Educational Conference was held at San Francisco, from June 28th till July 6th, as a section of the World Conference on Education. The Health Conference was called in the name of the American Medical Association, the National Education Association, the American School Hygiene Association, and the American Child Health Association. Official delegates were sent by twenty-four countries, including Armenia, Belgium, Canada, Chile, China, Costa Rica, Denmark, France, Hawaii, India, Italy, Japan, Norway, New Zealand, Peru, Scotland, Spain, Switzerland, Poland, Turkey, and Uruguay. All the leading social welfare organizations of the United States were represented, and there were many famous authorities on science and medicine to address the audiences.

The two chief problems discussed at the conference were the health education of the child in the schools, and the training of normal students and teachers to instruct in health matters. These questions were discussed from every angle—nutrition, physical education, home economics, school administration, school nursing, and medical and dental work.

When one realizes that it was only five years ago that the health education movement was inaugurated in a nation wide campaign, it goes without saying that this movement has been a great success when it can command international attention. At that time the Child Health Organization of America, now the Health Education Division of the American Child Health Association, started a campaign to interest teachers in the teaching of health habits to children in the schools. The public heard of this through baby contests, health play, school lunches, and the like, and the idea has been developed until health education has become a part of the curriculum of every school of importance in the country.

DR. SHEEHAN'S ARTICLE ON PLASTIC SURGERY

In the article on Plastic Surgery of the Face and Neck by J. Eastman Sheehan, M. D., in the last issue of the JOURNAL, many of the illustrations were omitted due to lack of space. These illustrations will appear in the author's reprints. Dr. Sheehan is one of the surgeons on the staff of the International Clinic of Plastic Surgery. Fig. 1 of his article was taken from Kilmer.

News Items.

Dr. Walker Honored.—The Women's Medical Association of New York City gave a dinner in honor of Dr. Jane Walker, of London, England, on Wednesday evening, December 5, 1923, at the Hotel Commodore.

Bronx County Medical Society Celebration.—The decennial banquet and dance of the Bronx County Medical Society will be held on January 9, 1924, at 7 p. m., at the Concourse Plaza, 161st Street and Grand Concourse, New York.

Dinner for Health Officers.—The Rockefeller Foundation gave a dinner at the Hotel Commodore in honor of a group of health officers representing eighteen foreign governments, who for the past three months have been in the United States under the auspices of the health section of the League of Nations for the study and observation of various types of public health organization. Dr. George E. Vincent, president of the Foundation, presided.

January Lecture Schedule.—The following lectures are listed for Friday afternoons at 5 o'clock at the New York Post-Graduate Medical School and Hospital: January 4th, the clinical use of basal metabolism, by Dr. Cameron V. Bailey; January 11th, radium therapy, with moving pictures, by Dr. George S. Willis; January 18th, a plea for a broader conception of dermatology, by Dr. Henry H. Whitehouse; January 25th, reconstruction surgery, with lantern slides and moving pictures, by Dr. Fred H. Albee.

Gouverneur Hospital Appointments.—At a meeting held by the board of trustees of Bellevue and Allied Hospitals, the reorganization of the medical service of Gouverneur Hospital was approved. Dr. Maurice Packard and Dr. Benjamin Schwarz were made medical directors to serve six months each; Dr. John Sheils and Dr. James Croce were appointed visiting physicians; Dr. I. J. Levy, Dr. H. Elwyn, and Dr. A. Hoffman, were appointed assistant visiting physicians; Dr. A. Fitzgerald and Dr. J. Stein were appointed adjunct assistant visiting physicians.

Foreign Correspondence.

LETTER FROM TOKIO

(From our own correspondent)

Tokio, *November 13, 1923.*

EXTENT OF DAMAGE FROM EARTHQUAKE

For nine miles along the north shore of Tokio Bay, and on both sides of the Sumida River which bisects the city, practically the whole of Tokio was wiped out, as a result of the earthquake and fire on September 1st. This includes six of the most densely populated wards of the city and the devastated area averages well over two miles in width. On the eastern side of the Sumida River, in the districts known as Fukugawa and Honjo, the poorer classes lived, but on the western side of the river, extending some places a mile into the heart of the most prosperous part of the city, were found a number of handsome residences and almost all of the wholesale and retail business districts of Tokio.

HOSPITALS DESTROYED

An estimate made about the middle of October gives the total value of buildings destroyed in Tokio alone of 1,463,790,000 yen; 224,567 houses were destroyed by the earthquake and fire, and of these 137 were hospitals of twenty beds or more. To appreciate what this meant in loss of hospitals to the city, one must remember that Tokio had only 236 hospitals before the fire with a total of 15,221 beds. A recent estimate of the 99 hospitals still standing gives the beds available at 8,559 at this time. Greater Tokio has a population of approximately four and a half millions. From this it will be seen that the actual number of hospital beds is much less than is the proportion in our large cities in the United States and abroad. It may be of interest in considering the question of the hospital facilities left available in Tokio to indicate the difference in the planning and organization of hospitals here in Japan as compared with the United States.

Before the recent catastrophe there were only three or four hospitals in the city with more than two hundred beds. The majority of the hospitals were really small nursing homes, conducted either by physicians for their own private patients, or connected indirectly with some teaching institution. Practically all of these hospitals were either two or three story frame or stucco buildings. The city authorities did not permit buildings for hospital service to exceed three stories in height. Largely for this reason, the percentage of deaths from the earthquake and subsequent fire was much lower than would have been the case if higher buildings of the Tokio type had been in use generally. Considering the violence of the first shock, and the promptness with which fire broke out in many parts of the city, the record of the number of patients saved is highly creditable to the faithfulness and prompt action of the staffs of the many hospitals throughout the city. In one centre near the University of Tokio, there were approximately twenty hospitals within a radius of half a mile, and every one of these hospitals was wiped out by fire. The University Hospital, an old building of the German pavilion type, spread over a large area, was not burned, but its laboratories were seriously injured and many parts of the buildings were practically destroyed. Baron Takagi's hospital in Shiba was entirely burned and this was also true of one of the largest private hospitals in the city, which has been conducted for the past seventy-five years by the Sato family, who for generations have been physicians.

DESTRUCTION OF ST. LUKE'S HOSPITAL

In St. Luke's Hospital we were exceptionally fortunate in saving all of our patients and the whole staff, including the servants. The hospital is in the centre of one of the most thickly populated districts of the city, protected on one side by the Sumida River. The building was of frame, three stories in height. At the first shake the building was badly damaged. Some of the stairways were so twisted and broken that patients could not be carried over them. In some places the walls bulged from the floors, leaving a gap of two or three feet, and floors sagged almost at right angles. There were about forty Japanese nurses on duty at the time, and with the prompt assistance of all the doctors and servants, the patients were hurried out of the building into the street in less than fifteen minutes. The violence of the shake was so severe that people literally staggered and fell on the streets and it is a remarkable tribute to the bravery of the staff that no accidents happened in the emptying of the hospital. The building was abandoned and the patients were taken across the canal which borders the old hospital lot, to the open parklike piece of property on the Sumida River, where the new St. Luke's Hospital was in process of construction. This lot covers approximately a city block.

During the afternoon fires raged all through the city but it was not until evening that Tsukiji, where the hospital stood, was threatened. Thinking the compound of the hospital perfectly safe, thousands of refugees poured into it from all parts of Tsukiji. In the immediate district, the first large building to be destroyed was the Hongwanji Temple, about four city blocks distant from the hospital. From this centre fires spread all through Tsukiji, and by ten o'clock in the evening not only St. Luke's was in flames, but the several residences of the staff, the school for nurses, and the dormitories which were grouped around the hospital buildings were all utterly consumed.

The crowds of people who had sought refuge in the hospital compound brought with them quantities of hand baggage in carts, rickshas and even by automobiles. These piles of baggage caught fire from flying brands, adding seriously to the terror and danger of the scene. Finally, so terrific was the heat that the hospital patients were lowered by the doctors and nurses into the concrete bays formed by the foundations of the new St. Luke's Hospital, in which several inches of rain water was standing. In these foundations, some five feet below the surface, the patients were kept the rest of the night, planks being placed over the foundation walls and over these blankets and *futons* kept wet by constant baling of water from the pits by the nurses and doctors, literally to keep them from being burned to death. Because the new hospital property had only a few buildings, and because all of these did not burn at the same time, only one or two people lost their lives in the grounds, but in Tsukiji, on the surrounding roads, many were burned. Also in the small gardens of private homes, where people had taken refuge thinking the gardens were safe, many lost their lives. Numbers jumped into the waters of the canal and the river for safety, and on to passing boats, some of which later caught fire and burned to the water's edge.

This story of the destruction of St. Luke's is more or less characteristic of the situation throughout the city during the night of fire. Few places had the wide area available here in St. Luke's for the protection of our patients, which accounts for the large loss of life in other hospitals in the thickly populated districts of the city.

TOTAL NUMBER OF DEAD

The total number of dead, according to the latest government statistics, is about 130,000, and the number of people still missing and unaccounted for is about 120,000, many of whom are probably dead.

NEW BUILDING REGULATIONS

The new municipal building regulations, issued since the fire, permit the erection of practically any kind of buildings for the next six months, with the provision that such buildings may be used for three years, and no permanent buildings may be erected for at least six months. This means that the hospitals which are able to afford any reconstruction are being put up in one story barracks, with small rooms for private patients, long narrow wards, and temporary operating equipment.

NO EPIDEMIC FOLLOWED DISASTER.

Although typhoid and paratyphoid fever has increased considerably during the past two months over the records of previous years, there is no widespread epidemic. This is true also of dysentery. The people are living much more in the open air than formerly because of the very poor housing conditions, and in some ways this may assist in the reduction of the curve indicating tuberculosis during the coming winter months and in the general well being of the poorer classes, as was the case after the disaster in San Francisco.

GIFTS OF HOSPITAL SUPPLIES AND EQUIPMENT.

The American Army brought in between five and six million dollars' worth of medical and surgical equipment and hospital supplies and food. The generous gift of drugs from the American Red Cross added to this hospital equipment will play an important part in meeting the present emergency, and also in equipping centres around which much of the hospital rehabilitation will be worked out. The Japanese Red Cross is building several barrack hospitals in different parts of the city, to be administered by their own staffs. These hospitals are to be maintained by the Japanese Red Cross for six months, when they will either be converted for private use, or removed to other districts of the city for housing facilities. In addition, the city of Tokio is establishing two small hospitals for maternity service and two for children, and a large number of milk stations throughout the city for undernourished children. Other plans are now under consideration for improving hospital facilities for the poorer sections of the city where the destruction of life and property was most severe.

It is stated that immediately following the earthquake and fire, approximately one third of Tokio's population left the city for surrounding country districts. Recently many of these people are returning. The chances are that during the winter months the needs for hospital service will be acute, and although the number of barrack hospitals now being erected will largely meet the situation, there must necessarily be considerable suffering from the lack of sufficient hospital accommodation and especially from poor shelter in the homes of the poorer classes.

PUBLIC HEALTH REFORMS PLANNED.

Up to the present, public health work in Japan has not been widely undertaken. The city authorities are now alive to the needs for this kind of work, and plans are under way to establish not only larger and better hospitals, but to institute fundamental reforms in the living conditions and housing of the mass of the people in the city so that better health conditions may prevail. These problems are much more difficult of solution here than in the United States, as the buildings in Tokio are of very flimsy construction, and with the narrow streets and overcrowding, it is almost impossible to enforce the necessary sanitary laws which the more progressive members of the medical profession in Japan wish to see put into effect.

The new Tokio will probably have much wider streets than formerly and an effort is being made to induce more people to live in the higher outlying territory which would assist in eliminating the congestion along the water front in the lower parts of the city.

LONDON LETTER.

(From our own correspondent.)

London, *October* 3, 1923.

HEALTH OF GREAT BRITAIN.

Sir George Newman, the chief medical officer of the Ministry of Health, issued recently the report of the health of the nation for 1922. In this report the somewhat interesting details of the state of the public health and of the steps to be taken to improve it are presented in a masterly and comprehensive manner.

There is no doubt that intense interest is being taken in other countries in the progress made by this country to improve the general health of the population. We are the pioneers in public health work and although in several respects America has passed us, the British Ministry of Health is an object of great concern in all parts of the civilized world. The inherent principles of public health are similar in all civilized countries, and the British annual report provides a lesson to all.

It is out of the question to attempt to deal with Sir George Newman's report at any length and only a few of the more important subjects debated will be referred to. In the first instance, it may be said that the campaign against infant mortality inaugurated in recent times continues to show good and encouraging results. Much remains to be done, but it has now been proved that, even in the most congested areas, when appropriate measures are set in motion infants and children thrive, and it is an excellent augury for the future when slums have been swept away and the conditions of life in crowded cities rendered more healthful. Tuberculosis and rickets, two diseases obviously largely the outcome of lack of sunlight and fresh air and of defects of food, are decreasing and will undoubtedly continue to decrease.

There are two diseases, however, which exhibit no signs of decrease but on the contrary are increasing. The first is cancer and the other diabetes. Figures are given in the report which indicate that cases of both cancer and diabetes are more numerous than ever before. While there does not seem to be any organic connection between these two diseases, evidence is accumulating that both are the result of errors in diet; at least so far as cancer is concerned, diet plays a part in its causation, and in diabetes diet plays an even more important rôle. It appears in fact that both are essentially diseases of civilization, but with regard to cancer, much has to be done before any dogmatic statements can be made. The laboratory method of investigating the cause of cancer has hardly come up to expectation, and if the Ministry of Health were to appoint a skilled committee to delve into the matter from the point of view of the habits of civilization, the step would be welcome. Moreover, such a procedure would tend to help laboratory workers, as the statistics gathered by a committee of this character would indicate the lines of research work to be followed.

Sir George Newman, in his report, refers to a paper on the possible influence of diet on the causation of cancer read recently by Dr. Monckton Copeman before the British Association for the Advancement of Science. Of course, if diet is an important factor in the causation and development of cancer there are definite forms of diet which are peculiarly calculated to aid in originating the malady, and by avoiding these foodstuffs, the disease may be prevented from gaining a hold, or its development may be stopped or checked. Up to the present time investigations and researches into the causation of cancer have been barren of any definite results, and therefore every line of research which suggests a clue should be thoroughly investigated.

A part of the report is concerned with smoke abatement, one of the most conspicuous evils of industrial civilization and an evil which is especially prevalent in this country. Legislation on the subject has been passed which has been more honored in the breach than in the observance. Sir George Newman now recognizes the gravity of the problem, stating that the injury done by smoke is constant and cumulative. He urges local sanitary authorities to act and it may be expected that effective measures will be taken to remedy an evil which has existed already too long to the great detriment of the general health.

POPULATION AND BIRTH CONTROL.

Among the many papers of interest read at the meeting of the British Association for the Advancement of Science was one dealing with birth control, a subject which is being widely discussed in this country at the present time. The population is increasing, while opportunities for gaining a living are diminishing. Unemployment is rife and until international affairs are more settled in this country, at any rate, this state of things is likely to continue. In order to relieve the situation several suggestions have been made, emigration to the Dominions being one of these. Unfortunately, this remedy has been shown to be of little use. In the first instance the Dominions wish for the best of the population only, those least to be spared. If emigration is to consist of the mentally and physically fit, schemes to aid emigration should be discouraged rather than encouraged.

A method of limiting our population to meet the altered situation was proposed some years ago, and in view of the conditions existing today the advocates of this scheme are more insistent than ever before. The method to which allusion is made is birth control. The desirability of restricting the size of families has been proposed by several well known men of science and members of the medical profession and appears to be finding a certain amount of favor with the general public. However, there is no space here to deal with the arguments for and against so debatable a question and only a passing reference will be made to an address given by Sir William Beveridge before the economical and statistical section on population and unemployment of the British Association. Sir William Beveridge attempted to prove that the increase of population in the British islands was neither dangerous nor abnormal, that the Dominions had room for all the surplus and that the war and that alone was responsible for the present distress. The paper was received with severe criticism from all sides and it was shown that statistics when applied to human beings were comparatively useless. It was pointed out, as mentioned previously, that while there is room in the Dominions for the surplus population of the country, the surplus mostly proceeded from the lower strata of society, which the Dominions are determined not to admit.

SLUMS AND DISEASE.

In the economics section of the British Association, Mr. J. J. Clarke, of Liverpool University, read a paper on the rehousing of slum dwellers. After giving details concerning overcrowding in various British towns and its disastrous results he suggested drastic measures to solve the problem. The gist of the scheme was that the unemployed of a suitable age should be compelled to serve in a military corps to constitute housing battalions on the lines of the dockers' battalions raised during the war. Prices of building materials should be fixed and where necessary materials should be commandeered. He said that these proposals might be considered as too drastic, interfering as they did with the liberty of the subject and striking at the foundations of all the economics of industry. If they were, the reply came from the depths of the slums and the haunts of men which permitted of neither decency nor morality.

THE SUPPLY OF INSULIN IN GREAT BRITAIN.

Professor J. R. McLeod, in whose laboratory Dr. Banting and his coworkers made their researches in diabetes, read a paper on the question before the meeting of the British Association. After saying what insulin could and could not effect, he stated that successful endeavors had been occasionally made to extract insulin from yeast. However, the yeast extracts were not consistently successful. It was surmised that in the course of bacterial action in certain yeasts one of the constituents of insulin was formed. He remarked that with reference to the future supply of insulin the sources in Great Britain were quite inadequate. The unit price would become lower as production increased. The action of the British Medical Council had assured to this country an adequate supply of guaranteed potency.

LATIN AMERICA LETTER

(From our own correspondent)

Balboa Heights, *November 19, 1923.*

UNUSUALLY HEAVY RAINFALL.

Heavy rains over the watershed of Gatun Lake on October 21st and 22d caused a rate of run off into the lake not previously attained since the opening of the canal and brought about an interruption of traffic on October 23d, when no ships were allowed to begin the transit of the canal between 6.30 a. m. and 3.30 p. m. The interruption was due in part to a strong current at Gamboa, where the waters of the Chagres River reach the canal channel, and in part to the use of the lock culverts to discharge excess water from the lake. Eleven gates of the spillway were opened and when the flood was at its height, the sidewall culverts at Gatun and Pedro Miguel locks were also opened.

The average dweller of the United States has no conception of what Nature can do in the way of rain once she sets her mind to it. The following table setting forth the rainfall in inches for a single week demonstrates the logic of the Isthmian superstition that children born in the rainy season have gills:

	21	22	23	24	25	26	27	Total
Colon	2.62	4.45	8.71	6.13	5.73	4.00	4.16	35.95
Gatun	3.02	2.85	9.34	8.66	4.05	2.24	4.79	35.17
Monte Lirio	4.21	2.54	9.67	4.95	4.72	2.88	5.81	34.97
Gamboa	1.20	1.54	5.94	3.31	2.80	.72	2.56	18.47
Alhajuela	.70	1.26	8.09	7.15	2.69	.37	1.63	21.50
Vigia	.16	1.07	...	...	...	...	2.14	21.91
Empire	...	...	...	3.30	1.80	.04	1.06	6.24
Culebra	...	...	4.20	2.72	2.33	.30	1.10	10.65
Rio Grande	...	...	...	2.34	2.03	.30	.88	5.55
Pedro Miguel	.44	.70	3.85	2.39	1.70	.16	.73	9.83
Balboa Heights	.27	.51	3.38	1.62	1.46	.05	.35	7.76
Balboa	.24	.48	3.26	1.95	1.53	.07	.37	7.90

In the United States a two inch rainfall is considered as heavy and .02 inch is hardly a sprinkle. If an area gets a two inch rain the water would be two inches deep if the ground were perfectly flat and no water sank into the ground; an ordinary farm of 160 acres would have 1.2 million cubic feet of water on it, a weight of 36.2 thousand tons. This would equal a lake 5 feet deep, 500 feet long and 464.6 feet wide. If this volume of water had to flow by one place in a stream three feet deep, in one hour at the speed of an ordinary stream, about two feet per second, a creek fifty-four feet wide would be formed. Reference to the foregoing table shows that at Colon, Gatun and Monte Lirio it rained more than two inches for a week and that the total rainfall in each instance almost equalled three feet. It is, therefore, not surprising that the surface of Gatun Lake rose from an elevation of 86.10 feet above sea level on October 21st to a maximum of 87.48 in the early morning of October 23d. This represents an increase in storage of six billion cubic feet. The discharge through spillway and lock culverts aggregated one hundred and seventy-five thousand cubic feet a second. It is estimated that at the height of the flood the water was entering the lake at approximately three million cubic feet a second, but as the heavy discharge had been begun early there was a margin of space sufficient to keep the final elevation within bounds. This was accomplished by having the meteorological stations up the Chagres River make constant telephonic reports of the amounts of precipitation, thus permitting the regulation of the spillways so as to discharge an amount of water which would keep the lake at a safe level. The fall of water was so great that the Chagres reached an elevation of 117.4 feet at Alhajuela exceeding its elevation at any time since 1909 when a flood record of 121 feet was set.

The situation was aggravated locally by small slides and washouts on the Panama Railroad, a break in the water main from the Chagres River, supplying Panama City and the towns at the Pacific end of the Panama Canal, and a break in the transisthmian duct line which interrupted telephone, telegraph and cable communication. Fortunately, no damage was done to the locks, spillways or the hydroelectric plant and in spite of all the difficulties which the enormous downpour created, the passage of ships through the canal was delayed only nine hours at the height of the flood on October 23d and for a brief period late in the afternoon of October 24th.

On the morning of October 28th, after it was believed that all the troubles resulting from the flood were over, a slide involving about three hundred thousand cubic yards of material developed on the west bank of the canal north of Culebra. It was approximately 1,100 feet long and at the point of greatest encroachment extended 150 feet into the channel. Ships were delayed only a few hours and there has been no enlargement of the slide since. Dipper dredges were immediately put to work clearing the channel and it is estimated that they will have completed their work by December 1st.

The employees of the Panama Canal met the emergencies caused by the terrific precipitation and demonstrated that the spirit which built the canal is maintained at its former level.

LANDSLIDE THREATENS HOSPITAL GROUNDS.

Three thousand cubic yards of earth and rock crashed down from the top of Ancon Hill during the heavy rains of October 9th, pushed through the rear concrete wall of the Ancon Hospital's bakery, swept through the carpenter shop adjoining the bakery and was stopped by the rear wall of the isolation ward where twelve patients were confined at the time. No injuries occurred. The lower ward of the isolation building was covered with six feet of earth, rock and fluid mud and the elevator machinery and the elevator itself were completely buried. The accident occurred about 3.30 in the afternoon during one of the heaviest downpours of an unusually rainy season, and is believed to have been caused by the sliding of a mass of earth and débris thrown out from the cut for the new army road which skirts the hill above the hospital grounds. Gangs of men, trucks and all necessary tools were rushed to the spot and after forty-five hours of continuous labor and the use of hydraulic mining, the gigantic mass of material which threatened the boiler house and the operating pavilion was completely removed.

Book Reviews

GASTRIC ULCER

Les Ulcères perforés de l'Estomac et du Duodenum. By H. Monder et G. Lauret. Paris: Masson & Cie, 1923.

Mondor and Lauret give a detailed description of the present day status of perforated gastric and duodenal ulcers. While in 1890 perforated peptic ulcers gave a mortality of one hundred per cent., very soon afterward surgery stepped into this field and the prognosis began to improve very rapidly. From 1890 to 1900, the mortality fell to seventy-five per cent., and from 1900 to 1910 to about thirty per cent. Nowadays the mortality fluctuates between ten and twenty per cent. The main point at issue is an early diagnosis and an immediate operation. The sooner after the perforation the patient is operated upon, the better the prognosis. Operation ten to twelve hours after perforation almost always leads to recovery, and operation after thirty-six hours gives a bad prognosis. The monograph is interesting and highly commendable.

THE COLON

Les Colites. By Prof. Paul Carnot, Dr. Paul Harvier, Dr. R. Frichl and Prof. Lardennois. Paris: Bailliere et Fils, 1923.

Contrary to the views of Metchnikoff and Arbuthnot Lane, that the colon is the cause of many evils, and that without this organ everybody could be happier and live longer, Carnot considers the large bowel as a very useful organ without which a perfect elaboration of the digestive process is hardly possible. The right portion of the colon serves to utilize remaining nutritive material and fluids, while the left portion is destined to serve as a reservoir for the fecal matter until an appropriate time for its evacuation.

Catarrhal, parasitic and ulcerative conditions of the colon are all minutely described and their treatment given. The monograph can be highly recommended.

BACTERIOLOGY

Principles of Bacteriology. Arthur A. Eisenberg, A.B., M.D. Second Edition. St. Louis: C. V. Mosby Company, 1923.

Of necessity a book containing 214 pages cannot be too exhaustive in its treatment, especially when an effort is made to cover so much ground as the present volume does. In preparing the text, which has been used for the teaching of nurses, the author states in his preface that he takes nothing for granted and leaves nothing to one's imagination, which is an uncommonly wise principle, considering the purpose for which the book is designed. The language is simple and easily comprehensible. The fact that the chapters in the second section of the book, dealing with special bacteriology, range from a half page to ten pages in length, is not a detriment to the book, but may rather be considered an advantage, because it demonstrates that Eisenberg has not attempted to make medical students and diagnosticians out of his pupils, a tendency which is much too prevalent, judging from the recent type of texts written for training schools. In teaching bacteriology to nurses, it is possible to show them only the high lights of the subject; they cannot be expected to attack it from the same viewpoint as the second or third year medical student, and such an approach can successfully be accomplished by the principles of bacteriology. Occasional typographical errors occur, as for instance, on page 100, Lubs's name is incorrectly spelled, but these are altogether minor matters.

LIVER ABSCESSES

Les Hépatites amibiennes et leur traitement. By Dr. F. Francon and Dr. J. Hutinel. Paris: Gauthier-Villars & Co., 1923.

Most of the liver abscesses are due, according to Francon and Hutinel, to amebic invasions. The amebæ are most numerous in the wall of the abscess, less so in the abscess cavity. The amebæ in the liver are never found in the cystic form. For this reason the treatment with emetine is most effectual and can be carried out successfully. The present monograph is a useful addition to our knowledge of liver pathology.

ROCKEFELLER INSTITUTE STUDIES

Studies from the Rockefeller Institute for Medical Research. Reprints. Volume xlv. 1923.

The present volume contains the reprints of forty-eight papers which have appeared in various medical journals recently, many of which have been abstracted in this Journal. The volume is representative of the type of work carried on at the Rockefeller Institute, and includes papers on pathology, bacteriology, chemistry, experimental surgery, general physiology, animal pathology, and some studies on diabetes, quinidine, arthritis, etc., from the hospital of the Rockefeller Institute.

CHEMISTRY FOR NURSES

A Textbook of Chemistry for Nurses. By Fredus N. Peters, A.M., Ph.D. Second Edition. Illustrated. St. Louis: C. V. Mosby Company, 1923.

The author has presented his subject in a very human and understandable fashion, and apparently great care has been taken in writing it so that it should not be over the heads of pupil nurses. Much of this result is accomplished by the many references to the practical chemistry of everyday life with which the nurse is familiar, although she may not have recognized that the science of chemistry was in any way involved. Each chapter contains at the beginning an outline of the matter to be studied, and at the end, a number of exercises for review.

OPHTHALMOLOGY

The Ophthalmology of General Practice. By Malcolm L. Hepburn, M.D., Lond., F.R.C.S. New York: Paul B. Hoeber, 1923.

In this little volume Hepburn gives considerable varied information to aid the general practitioner in distinguishing between cases which he can treat himself and those which he must refer to a specialist. Considering the large field of this subject and the interrelations of ophthalmology with questions of infection and immunity, neurology, clinical medicine, endocrine disturbances, intracranial disease, and blood pathology, the wonder is not that so much has been omitted and slighted, but that so much has been included. Of this there is a marked inequality both in the practical importance of the topics chosen and in the manner of their presentation. Like the curate's egg, parts are very good. It is a question whether, in this country, at least, the patient "expects his medical man to be an expert in all branches of medicine and surgery." The latter may be excused for ignorance of guttate choroiditis, retinal detachment, and hyphemia, all of which are discussed by Hepburn, if he knows something about the ocular complications of the infectious diseases of childhood, the eye symptoms of accessory sinus disease, and the rôle of ametropia and defective vision in school life, which are treated all too briefly.

Medicoliterary Notes.

An attractive booklet called *The Doctor's There, a Note of Appreciation,* is being distributed by the G. W. Carnrick Company, manufacturing chemists, of this city. It contains several poems by well known writers, paying tribute to the work of the physician, and a number of prose paragraphs on the same subject from such noted authors as Robert Louis Stevenson and Ian Maclaren. The selections are aptly illustrated with reproductions from line drawings.

* * *

Birth Control, What Is It? is the title of one of Small, Maynard & Co.'s new books. The author is Dr. Lydia A. De Vilbiss, of the United States Public Health Service. Dr. Adolf Meyer, in a foreword to the volume, calls it "a wise and temperate picture of the facts to be considered, of the limitations of our present means of education and methods of procedure and of the existing laws, and of the most sensible lines along which progress can become fruitful. . . . A carefully considered, documented and authoritative work on a subject in which the American public is increasingly interested."

* * *

Chronologia Medica, a Hand List of Persons, Periods and Events in the History of Medicine, by Sir D'Arcy Power and C. J. S. Thompson, is a small volume of 300 pages recently published by Paul B. Hoeber. It begins with about 5000 B. C. and ends with the death of Röntgen in 1923. Such a compact yet inclusive reference book on the history of medicine fills a long felt want.

* * *

The National Health Council has prepared a list of health films, which is a combination of lists sent in by health and welfare organizations, state boards of health, and producers and distributors of films. It includes the title, number of reels, the name and address of the distributor, the price, and a brief synopsis of each film. The list includes such subjects as child hygiene, public hygiene, communicable diseases, other diseases, nursing, anatomy, physiology, and first aid.—*Mental Hygiene Bulletin.*

* * *

A note in the *American Journal of Public Health* describes an ingenious method used in California in an attempt to abolish the use of roller towels in hotels. A sticker was devised, carrying a message as follows: "Roller towels may spread disease. This hotel is endangering your health and is violating the State Law of California." These stickers were furnished to traveling men through their societies, who cooperated eagerly. The demand for stickers was tremendous, with the result that within a very short time hotels all over California saw the light and abolished the roller towel.

* * *

Quebec was the first place in the world to initiate the Junior Red Cross movement. The idea originated with the Red Cross Society of the Province of Quebec in 1914, who enrolled children to help in the making of surgical dressings and other material for the comfort of the troops in the field.

* * *

Norah Hill has an interesting article entitled The Great God Play in the *World's Health* for August. She tells how the playground and recreation movement has spread, thanks to various agencies, among them the Junior Red Cross and the American Playground and Recreation Association, throughout almost the whole of Europe where there is such dire need of things pertaining to the lighter side of life.

* * *

A significant step forward in sanitary practice should follow the publication of a tentative report on plumbing by the United States Department of Commerce. The ultimate purpose is toward simplification and standardization of plumbing regulations. When those interested have had an opportunity to study this report, a model plumbing code will be prepared and submitted for consideration.

* * *

The Nation's Health for August is a number of unusual interest. Among noteworthy articles are: The Cripple's Place in Society Through the Ages, by Dr. Alexander Horwitz, who considers the cripple's worst handicap to be the social horror of deformity which produces a bitter introspection; A Scheme for Classification of Delinquency in Children, by Dr. Franklin G. Ebaugh, of the Philadelphia General Hospital; Organizing to Salvage the Mental and Nervous Derelict, by Dr. Joseph Smith and Jacob A. Goldberg, of New York City; and Practical Methods for Removal of Dust and Fumes, by H. H. Valiquet, who describes how the chemist and engineer must work jointly to detect and remove at its source the health hazard from air pollution.

* * *

Southern Italy has almost completed what is probably the most extensive water supply system in the world—the Apulian aqueduct, which it has taken sixteen years to build. The trunk and branches have a total length of 993 miles and supply 266 communities scattered over an area of 8,100 square miles, and having a population of about three million.

* * *

As far back as the year 1580, Queen Elizabeth issued an edict prohibiting the burning of certain fuels in London because the health of her knights might suffer by having to breathe smoke and fumes. It is even recorded that a man was hanged for burning coal that smoked inordinately.—*Weekly Bulletin, Chicago Health Department.*

Practical Therapeutics

ZINC IONIZATION IN EAR, NOSE, AND THROAT DISEASES*

By Joseph B. Kanter, M. D.,

Brooklyn,

Attending Otolaryngologist, Brownsville and East New York Hospital, and Hebrew Home and Hospital for Aged, of Brooklyn. Formerly Instructor in Laryngology, New York Polyclinic Medical School and Hospital.

The treatment known as ionization consists in the introduction of various ions into the tissues of the body by means of the galvanic current. It may be divided into medical and surgical. By medical ionization we mean the introduction of various ions into the body for their constitutional effects or for their mild local effects. Experiments carried out on animals prove that ions can be carried into the body by means of the direct electric current and cause constitutional effects. Thus lithium and iodine ions have been made to penetrate the skin and have been detected in the urine and saliva. Likewise, the strychnine ion can be made to pass through the skin and cause convulsions, and the cyanide ion can be similarly introduced and cause rapid death. The entry of these substances is not by diffusion, because the mere application of these substances to the skin will produce no effect; nor are they effective if the pads are connected to the wrong electrodes.

The local effect of ionization is seen when an ulcer is treated by zinc ions. The application of a dilute solution of zinc sulphate to the ulcer produces no visible effects. But if the same solution is placed on a gauze pad connected to the positive pole of the galvanic current and the latter allowed to pass for ten minutes, the granulation tissue is seen to acquire a pearly white color, not only on the surface, but in the deeper parts. The white color is due to the coagulation of the albumin forming a compound of albumin and zinc.

By surgical ionization, also called electrolysis, we understand the use of the electric current for the destruction of tissue by caustic action of the ions. All tissues of the body contain water and sodium chloride. When the galvanic current is passed through the tissues of the body, if the positive electrode is of platinum hydrogen ions are formed and liberated at the anode and hydroxyl ions (OH) at the cathode. In addition there is some free hydrochloric acid at the anode and sodium hydroxide at the cathode. These ions and molecules have a caustic action. If the positive electrode is of zinc or copper, then zinc or copper ions are formed at the anode instead of hydrogen, and if concentrated, these ions act as caustics. When the electrodes are in the form of needles the current is concentrated, and when the needles are inserted into the tissue the current is still more concentrated, and the caustic action of the ions and the molecules is most effective and destruction of tissue will follow. This destruction of tissue is really accomplished by chemical action of the ions and molecules on the tissue. The advantage of this method is that by regulating the amount of current we can destroy as little or as much tissue as desired and the action is thus localized and under perfect control.

Medical and surgical ionization are really identical, the chemical action in both is the same, the difference being only in degree, the former being less and the latter more concentrated. Surgical ionization or electrolysis is successfully employed in the removal of superfluous hair, nevi, warts, benign and malignant tumors. Similarly, polypi in the nose and ear can be destroyed, and hypertrophied turbinates cauterized by this method. Medical, or the less concentrated method of ionization, has also a great field of usefulness. All chronic purulent conditions, in whatever part of the body, are greatly benefited by zinc ionization. The success of this therapeutic measure depends upon the accessibility of the part to be thus treated. Dr. Samuel Sloan, of England (1), is employing zinc ionization in the treatment of the female genital organs, and has devised a special apparatus for the ionization of the vagina, cervix, and body of the uterus. Elkin P. Cumberbatch (2) quotes Wallace, Ironside Bruce, Herschell, and Curtis Webb as using zinc ionization for the rectum and colon.

The use of zinc ionization in the treatment of diseases of the ear, nose and throat is not new, yet the literature on this subject is exceedingly meager. The first to employ this method was A. R. Friel in 1913 (3). He used one per cent. zinc sulphate solution and obtained excellent results. L. Kesteven, in 1917, employed thirty per cent. zinc iodide solution in all cases of middle ear catarrh, functional deafness, tonsillitis, and hypertrophy of the inferior turbinate. He also states that he has obtained good results in acute purulent otitis media and acute rhinitis. Iodine being an anion and zinc a cation, he reversed the current occasionaly to obtain the benefit of both the zinc and iodine ions (4).

Dr. Friel, during a number of years, has found that zinc ions alone are capable of arresting the purulent process in the middle ear and the nasal accessory sinuses and permanently curing the conditions. The zinc ions remain active in the tissues after the flow of the current has ceased, and exert their action for some time, so that the introduction of the iodine ions and the reversal of the current are not at all necessary. I have tried the zinc iodine solution in several cases and found it had no advantage over the zinc sulphate.

The zinc ions may be introduced by using a zinc electrode connected to the positive pole. When the current flows the metal passes slowly into solution and the ions are formed. This, however, would require a stronger current than the patient would tolerate, as well as more time. The best results are obtained by using a zinc wire as a positive electrode and a solution of zinc sulphate. I found the solution used by Friel very satisfactory. It consists of zinc sulphate 3.75 gms., glycerine sixty gms., and water two litres. A stronger solution is of no advantage.

---

*Read at a meeting of the East New York Medical Society, October 18, 1922.

Elkin P. Cumberbatch in his book on medical electricity (2) states that "It must not be thought that more ions will be introduced if the solution is stronger, the stronger the solution the larger the proportion of undissociated molecules."

Regarding the penetration of the ions in the body, the same author has this to say: "The use of the electric current for the introduction of ions has this limitation—only the more superficial tissues receive them in numbers sufficient for therapeutic action. The deeper the part that requires treatment, the smaller the number of ions it receives. The lines of flow of the current diverge, and the ions take similar divergent paths, and so spread farther apart as they penetrate the deeper tissues. Other ions enter the blood and lymph streams and are carried away; still others combine with tissue ions and form insoluble compounds, and therefore pass no further." Also, the penetration of the ions depends upon the strength of the current, and the length of time the current is passing. Few patients can tolerate more than four ma. and with this strength of current, deep structures cannot be saturated with ions in any length of time.

Among the diseases in which zinc ionization is of special benefit are chronic purulent otitis media and chronic empyema of the frontal, maxillary and sphenoid sinuses. In acute purulent otitis media, the whole thickness of the mucous membrane is involved. The mucosa is edematous, and there is an exudation into the interstitial tissue which causes a swelling of the mucous membrane to the extent of several times its normal thickness. The antrum is usually involved, and often also the mastoid cells. The disease, therefore, is within the mucous membrane, and the bacteria are situated in the cells of the mucosa.

In chronic purulent otitis media the disease process is superficial, on the mucous membrane. Bacteria are in the pus only, not in the living tissue of the mucous membrane. The mixture of pus and bacteria fills the middle ear cavity and adheres to the superficial layer of the mucosa. The bacteria and their products, and the decomposition products of the serum and leucocytes, irritate the tissues with which they are in contact, and these latter respond by secreting more leucocytes and more serum. But the tissues beneath the superficial layer of cells are not involved and these form a wall of healthy living tissue. In other words, in chronic purulent otitis media the disease is in the discharge rather than in the tissue.

The same pathology obtains in affections of the nasal accessory sinuses. By means of free drainage and frequent syringing in some cases of middle ear suppuration and chronic empyema of the nasal sinuses the patients recover, but in a large number of cases they do not, and no amount of antiseptic and astringent drops and lotions will succeed in curing them. By means of syringing and free drainage we can remove the discharge but we cannot remove the microscopic layer of pus and bacteria that adheres to the surface throughout the whole middle ear cavity, and no drops or powders can be made to reach every part of the suppurating surface. In such cases zinc ionization is very effective. The results are invariably rapid, complete and lasting. The discharge ceases after a few applications and the ear remains dry.

In order to obtain these results it is essential that the zinc solution fill the entire suppurating cavity and come in contact with every part of the infected mucous membrane, while the current is flowing. In middle ear suppuration the opening in the drum must be large enough to allow the solution to pass freely into the middle ear. Polypi and granulations that obstruct the free entrance of the solution into the middle ear should be removed before ionization is attempted. This can be accomplished by surgical means, with the snare or curette, or by electrolysis. Cholesteatomata should be thoroughly removed before the application of zinc ionization. Chronic running ears due to constant reinfection through the eustachian tube, from purulent rhinitis and pharyngitis, or due to diseased tonsils and adenoids, cannot be permanently cured by ionization unless the causes of reinfection have previously been removed. Chronic rhinitis and pharyngitis must first be cleared up before ionization is attempted. Large and diseased tonsils and adenoids may not in themselves prevent the cure of chronic middle ear suppuration by ionization, but they may cause a reinfection of the middle ears, and it is advisable to remove these sources of infection first.

If the disease has involved the attic or mastoid the zinc solution cannot be made to reach these parts, especially when they are filled with granulation tissue, and therefore ionization alone is not sufficient to clear up such cases. Inflammation of the external auditory canal resulting from constant irritation from the pus from the middle ear is also benefited by ionization. To complete the cure, insufflation of an antiseptic powder in the external canal is of advantage.

Before citing cases it is well to outline the technic in the application of zinc ionization to the middle ear and nasal sinuses. The external auditory canal is wiped dry with cotton or, if thick pus is present, it is removed by syringing with hot water. The ear is then syringed with the zinc solution, and any air present in the middle ear removed by suction with the ear syringe. The patient is placed in the horizontal position, with the ear to be treated uppermost. A hard rubber ear speculum is inserted, filled with the solution, and the zinc electrode connected to the positive pole inserted. Care must be taken that the zinc wire does not come in contact with the wall of the external auditory canal, as otherwise a burning sensation will be felt by the patient at the point of contact of the wire with the skin.

As a negative electrode I use a steel spring three fourth inch wide made for me from a clock spring. It is shaped like the trousers holders used by bicycle riders with the binding post situated at about the middle of its convex surface. I have a number of such springs of different sizes to fit the wrists or legs of patients. In adults I apply the springs to the wrist and in children to the leg. The part is first covered with a thick layer of gauze saturated with salt solution and the spring applied.

The current is then started from zero and slowly and gradually increased until the maximum is reached—about three milliamperes. The current is allowed to flow for ten minutes and then slowly and gradually diminished until it reaches zero. The sudden increase of the current or its sudden decrease may cause a shock to the patient and should be avoided. The galvanometer should be watched during the time the current is passing through the patient, as without increasing the strength of the current the milliamperemeter needle may show a spontaneous and gradual increase in its strength. This is because the penetration of the zinc ions increases until the mucous membrane becomes saturated with them; this reduces the resistance of the tissues to the passage of the current. Sometimes the zinc ions form insoluble compounds with the tissue ions so that the current conducting ions are diminished in number and the milliamperemeter shows a reduction in current. The current should not be allowed to diminish below two ma. It may be increased to four ma. if the patient can tolerate this strength.

The zinc solution in the ear speculum must also be watched; if the eustachian tube is patent, the solution will run out through the tube into the pharynx and the milliamperemeter needle will move back towards zero, because there will be no conducting solution in the speculum. In such cases the solution must be constantly added so as to keep the speculum full. If the current is not increased above four ma. the patient experiences no pain. Some patients become dizzy and even vomit from stimulation of the labyrinth by the galvanic current; but this condition passes off in a few minutes.

The maxillary sinus can be ionized through an opening below the inferior turbinate. The antrum is irrigated, all pus removed, and then filled with zinc sulphate solution. The zinc wire can be introduced through either a hard rubber eustachian catheter or through a soft rubber tube. A better method is by drilling an opening in the anterior or facial wall of the antrum with the Halle trephine, as in the Canfield operation on the antrum. Through this opening the antrum can be inspected with an ear speculum, or, better still, with an electric auroscope, and if any polypi or granulations are present they can be removed with a curette before ionization is attempted. Through a vulcanite ear speculum, the zinc electrode can be introduced after the antrum is irrigated and filled with the zinc solution.

The other nasal sinuses can be ionized by Dr. Friel's method as follows: A small air balloon is introduced empty into the posterior choana or posterior nasal space and then inflated to close the opening. The frontal or sphenoid sinus is then filled with the solution, and a zinc wire, protected by a coat of collodion or a thin soft rubber tube, inserted into the sinus. Or the whole nostril may be filled with the solution, and the zinc wire introduced through a vulcanite ear speculum, thus ionizing the whole nasal cavity including the sinuses.

Nasal polypi should be removed, and if the ethmoid cells are involved they should be exenterated. Very often it is necessary to correct a deviated septum and remove the anterior end of the middle turbinate before the frontal sinus can be entered. According to Professor Hajek the frontal sinus cannot be probed in fifty per cent. of cases, and the proportion of cases that can be ionized without operative interference is considerably less than that. Therefore ionizing the sinuses through the anterior nares is a much simpler procedure, though the results are not so satisfactory.

During the past four months I have applied zinc ionization in fifty-two cases of chronic purulent otitis media, all private. The duration of the disease was from three months to fifteen years. In thirty-four cases the disease was confined to one ear. Of these cases five patients did not appear for a second examination. Of the other twenty-nine, all of whom called at my office between three and five days after treatment, twenty-one had perfectly dry ears, after the first treatment. In four cases the ears were dry after the second application. In two cases the ears dried up after the third treatment; in one case, after the fourth treatment; and in one case, that of a child of two years, the patient failed to respond to six treatments. This patient had diseased tonsils and adenoids and a mucopurulent discharge from the nose. Subsequent to the removal of the tonsils and adenoids the ear cleared up without any further treatment.

In eighteen cases there was chronic suppuration of both ears. In eight of these, both ears were dry after the first treatment; in two, after the first treatment of one ear and the second treatment of the other; in two cases, after two applications to one ear and three to the other. In one case one ear dried up after the first treatment, and the other after the fourth treatment. In another case, one ear remained dry after three applications and the other ear was still running after five treatments, the cause for which could not be ascertained. Four patients did not return after one application to each ear.

Tabulating the findings given above, we obtain the following:

Number of ears treated (thirty-four, disease in one ear; eighteen, disease in both ears)......	70
Results not known (did not return after first treatment)	13
Number of ears, results known.................	57
Ears dry after first treatment.................	40
Ears dry after second treatment...............	8
Ears dry after third treatment................	5
Ears dry after fourth treatment...............	2
Not improved (this includes case that cleared up after tonsillectomy)........................	2

Among the cases were three that had polypi which I removed before applying ionization. Also one case in which the ear was running two years after a radical mastoid operation was performed. I also applied zinc ionization in a number of cases of acute purulent otitis media, but the results were not definite. Perhaps the disease process was shortened, but no proof was possible. I do believe, however, that in the declining stage, if the opening in the drum is sufficiently large to admit the zinc solution, a cure is hastened by ionization. I also applied zinc ionization in two cases of empyema of the antrum both of which cleared up after the first treatment.

From the foregoing statements it is seen that over seventy-five per cent. of cases of chronic purulent otitis media are cured after one application of zinc ionization, and over ninety-five per cent. after one to four treatments. A. R. Friel obtained similar results with approximately the same percentage of cures in 304 cases reported last February (5).

The question will now be asked; Is the cure permanent? Dr. Friel has this to say regarding it: "Zinc ionization is an antiseptic procedure. It is not a method for producing immunity. Immunity in these cases is a condition acquired as a result of infection or inoculation, and presumably the tissues in the ear have been inoculated to a considerable extent by the products of the germs which have been so long in contact with them. As a matter of experience, when the patient has recovered from the otorrhea by ionization, a recurrence is uncommon unless the patient gets a fresh infection by bathing or a severe cold" (6).

The great advantage of zinc ionization in chronic purulent conditions, especially in the ear, is that it is a simple procedure causing no pain and discomfort to the patient, requiring no elaborate apparatus, and, what is more important, is eminently successful in so large a percentage of cases. From the experience of those who employed this method for a number of years, as well as from my own short experience with fifty odd cases, zinc ionization ranks highest as a therapeutic measure in chronic suppuration of the middle ear and nasal accessory sinuses and deserves to be employed more extensively than it is at present.

A CONVENIENT METHOD OF CLEANING BLOOD COUNTING PIPETTES

By A. E. Renner, M. D.,
New York.

By using a rubber bulb ear syringe, whose end is cut of sufficient length to fit the end of a blood counting pipette, solutions can be more easily and safely aspirated by hand than sucked by mouth. A much greater force is also in this manner available and furthermore every procedure is directly visible in the bulb and throughout the calibre of the pipette. Alcohol and ether must be aspirated with caution, because of their deteriorating effect upon the rubber bulb.

With a little practice it is possible to judge the force that is necessary to draw up a required amount of fluid into the glass pipette. It has been our custom to fill the ear syringe with tap water preparatory to affixing its end upon the glass pipette. Thus the entire contents of the rubber bulb can be forcibly blown through the pipette and a very complete, gross cleaning of the pipette results. It may be necessary to repeat this maneuvre several times before all vestiges of blood are sprayed out.

When ether or alcohol is to be sucked into the pipette by means of the ear syringe, the latter is attached to the pipette, which is then inserted into the solution and the ether or alcohol are drawn up carefully so as not to go beyond the glass into the rubber bulb.

Finally, by allowing the syringe to suck some hot air from the flame of a Bunsen burner, it is again attached to the pipette end and by repeated pressure upon and release of the bulb, the hot air is forced through, completely drying its bulb and calibre. This method does away with using the mouth, at best not only an uncleanly, but also a dangerous procedure.

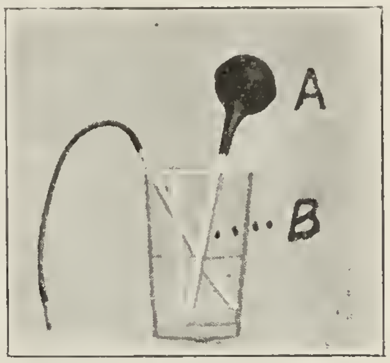

Fig. 1.—A, rubber ear syringe; B, blood pipette.

By dint of practice, the author has also been able to collect blood from a patient with the ear syringe and has adapted this method in preference to the rubber tube and bone mouth tip.

Symptomatic Treatment of Tuberculosis.—Edward O. Otis (*Boston Medical and Surgical Journal,* September 13, 1923) treats cough at first with simple remedies, such as chloroform water, or tablets, lactucarium, acacia, flaxseed tea, and sedative syrups, such as those of almonds and wild cherry. Inhalations or sprays are helpful if the upper respiratory tract is irritable; occasionally creosote may help. External applications, such as iodine, mustard plasters, or even a small blister, are other expedients; failing with these simple remedies, some form of opium will have to be employed. The socalled emetic cough after meals causing vomiting demands careful attention. The meal most frequently lost is breakfast and when this occurs the writer's practice is to give the patient on awakening a hot drink of some kind; this will excite the cough and the elimination of accumulated secretions and later breakfast may be taken with less danger of losing it. Sometimes a piece of ice in the mouth is of value, or chloroform or cocaine before meals. As a last resort, codeine or heroine an hour before meals may be required; if there is laryngeal irritation medicated inhalations may be tried, or an application of iodine and iodide of potash in glycerine to the pharynx every day or two. Hemoptysis is treated by ice in the mouth and an ice bag on the chest; if there is comparative hypertension the nitrites are indicated. If there is hypotension, adrenalin or pituitrin by hypodermic administration is indicated. Some opium is likely to be needed to allay cough and nervousness and prevent dislodgment of the forming clot. The one great treatment of fever is rest; the one drug employed is pyramidon in five or ten grain doses once in twenty-four hours. As to diet and avoidance of digestive disturbances, an ample mixed diet in three daily meals fulfills all requirements. Pain rarely has any underlying cause and is treated by mustard paste, iodine, heat, and dry cupping; of internal medications the most useful are salicylates, aspirin and phenacetine.

Letters to the Editor.

WOMEN IN MEDICINE

Brooklyn, N. Y., *December 4, 1923.*

To the Editor:

I have read with very great interest your editorial on Women in Medicine, which appeared in the issue of the New York Medical Journal for November 21, 1923.

You were kind enough to say that "on the whole women who have chosen the medical profession appear to have justified the selection of a career." You say, also, that "preventive medicine offers better facilities for women than ordinary practice."

You give to women the credit for being intuitive and admit "the great importance of this quality in diagnosis and prognosis when reinforced by training." You deserve credit for these laudatory statements but, do you not stultify them by subsequent statements not based on up to date knowledge of facts?

You say, "there are few women in general practice." The fact is, that the census of 1918 gives the name and address of more than seven thousand medical women in the United States, and the number in England is even larger, I believe, in relation to the small area covered.

You further limit them by saying "they appear *only* to be adapted for certain kinds of medical practice," and this lack of adaptability was shown during the war more with women than men." The facts are that a large number of medical women filled the places left vacant by medical men who served in military hospitals in this country, in England and in France. One woman physician, whom I know personally, carried on her own large general practice and that of her husband during the entire war, and this was done without either *mental* or physical breakdown.

Furthermore, the War Committee of the Medical Women's National Association, at the beginning of the war, raised funds, got together a body of medical women, surgeons, specialists and general practitioners, as well as a large corps of nurses, and sent them to France where they took the entire medical charge of the civilian population in the large district cared for by the Association for Devastated France. These doctors opened hospitals and clinics, conducted a weekly automobile clinical service in all the smaller towns of the region, sending doctors, nurses and medical supplies, and instruments for the treatment of the hundreds of sick people who swarmed into the rooms opened in town halls, etc., to accommodate these clinics. Hundreds of operations, major and minor, were performed in the hospitals by women surgeons, cataracts were removed, women dentists cared for teeth, and this work was continued till the end of the war, when the men physicians returned to resume the work.

Farther on in your article you say, rather apologetically, "In the factors which make for success in *any sphere* of life it may be that women are not as well equipped by heredity as men." If this were true, one would be tempted to ask, do women inherit nothing from their fathers?

Sir Humphrey Rolleston, from whose address at the Royal Free Hospital in London some of these statements in your editorial are borrowed, advises "women students to remember that they are more liable to mental breakdowns than men." In forty years of acquaintance with women medical students I fail to recall one mental breakdown among them, and it has long been known that women continue the practice of medicine to a greater age, as a rule, than do men.

The last bomb thrown at medical women in your editorial, whether manufactured across the Atlantic or in America, is, to say the least, filled with a poison gas, unworthy of its source. May I repeat it? "It would appear that here is a *definite place* for women in medicine *but* that at any rate in existing circumstances they are not nearly so well fitted as men to practice medicine. In the course of time a type of woman may be evolved who will equal man as a practitioner of medicine, but that time has not come yet."

I leave it to your readers to decide whether, as a matter of fact, this "is very laudatory" to women physicians, as you suggest in your letter to me.

Eliza M. Mosher.

PLEA FOR AID FOR LEIPZIG MEDICAL STUDENTS

Leipzig, *October 9, 1923.*

To the Editor:

The miserable plight of the majority of the Leipzig student body forces us, with heavy heart, to make known to the good people in foreign countries the conditions here and to implore them to help us. Because of the dreadful money values, a great many of our young medical students do not know what they shall do to finish their studies which they undertook under better conditions. With almost superhuman strength they conduct the fight for their existence, and do not stop at any kind of work, in mine or factory, but the undernourished body frequently cannot stand the hard labor, and they can consequently do little studying.

Germany needs today more than ever to educate the sons of the middle class, from which so many intellectuals and physicians have come. If students of this class are deprived of education we lose something that is irreplaceable. In our residence an endowment through the will of a deceased philanthropist has been established for worthy needy students. These students receive from this benefit fund, in amounts according to his needs, textbooks, paper, food, clothes, etc. In this way every cent of the money goes to the neediest and is used to best advantage.

I cannot say in words how grateful we would be if you or your friends would send us help in our work to aid these students. In this way you would also render the students and the country an inestimable service.

(Signed Dr. med. Werner Spalteholz,
Professor an der Universität
Mozartstrasse 21

Abstracts from Current Literature

INFECTIOUS DISEASES.

Observations on the Oculocardiac Reflex in Diphtheria.—Jesse G. M. Bullowa (*Archives of Pediatrics,* May, 1923) states that orbital pressure induces slowing of the heart by reflex stimulation of the vagus. In severe diphtheria intoxication, the heart is frequently refractory to vagus inhibition. Failure of the heart to respond by slowing, on stimulation through the vagus, as by orbital pressure, indicates either a refractory heart muscle or such an intoxication of the sympathetic that the vagus is already unopposed. True vagus paralysis does not occur in diphtheria.

Intravenous Injection of Diphtheria Antitoxin.—Paul Iversen (*Lancet,* April 7, 1923) asserts that the intravenous injection of diphtheria antitoxin is not a dangerous method. It should be the method of choice, even in patients who have previously received serum. It is only necessary to give the injection slowly, and temporarily or definitely discontinue it on the appearance of any reaction on the patient's side. The most unfavorable attacks after reinjection occur at the time when the serum rash appears.

Serum Phenomena and Their Relationship to the Prognosis of Diphtheria.—G. W. Ronaldson (*British Journal of Children's Diseases,* July-September, 1923) states that increased doses of the serum increases the incidence of serum manifestations, but diphtheria toxin exercises an inhibitory influence both on the frequency and the intensity of serum reactions. In very severe cases the rash is late in development, scanty, or entirely absent. The presence of a rash, even of the most limited nature, is a favorable sign. A good rash suggests a good prognosis. A case with a well marked reaction is not likely to end fatally, and the appearance of a rash affords some assurance that severe paralysis is unlikely. A primary rash is valueless in forming an estimate as to the likelihood of paralyses generally, its value being restricted to the severer forms. A secondary rash enables one to forecast with confidence that a patient will neither die nor suffer from a paralysis of any of the graver types.

Diphtheria Carriers.—F. W. Sumner (*British Medical Journal,* May 12, 1923) states that prophylaxis is a two edged sword. In an outbreak of diphtheria, prophylactic injections must be given to all contacts, but where antitoxin only is used, a crop of diphtheria carriers should be watched for. In a series of tonsillectomies, thirty per cent. were found to harbor diphtheroid bacilli in the tonsils. A considerable percentage of the public at large are probably diphtheroid carriers. From a clinical point of view there are three types of sore throat: 1, those with clinical manifestations of a diphtheritic throat and with positive bacteriological reports; 2, those with clinical manifestations of a diphtheritic throat but with negative bacteriological reports; and 3, those without clinical manifestations of a diphtheritic throat and positive bacteriological reports. The first two groups must be regarded as diphtheria and treated accordingly. The cases in group three are possibly and probably merely cases of some inflammatory condition of the nasopharynx and the bacilli found are nonpathogenic and noncausative of the condition. Clinically some of these cases must be considered and treated as diphtheritic.

Changes in the Streptococci Flora of the Throat During Diphtheria.—Lloyd Arnold (*Journal of Laboratory and Clinical Medicine,* March, 1923) reports a marked increase in the number of hemolytic streptococci in the throats of patients during diphtheria, at which time the streptococci have a limiting pH concentration differing from that of the normal throat flora, accompanied by an overgrowth of the types fermenting lactose and salicin. The strains that produce the limiting hydrogen ion concentration between pH 4.3 and 4.5 are considered by most investigators as of bovine origin, or nonpathogenes, and those reaching the lesser hydrogen ion concentration limits, pH 5.0 to 5.5 of human or pathogenic origin. If this is true the streptoccocic flora of the human throat can under normal conditions be considered as nonpathogenic types and the flora of the diphtheria throats as human or pathogenic types.

Twenty-five Cases of Whooping Cough Treated by Injections of Ether.—Angelica Panayotatou (*British Journal of Children's Diseases,* July-September, 1923) had occasion to treat twenty-five cases of whooping cough which occurred in an orphanage. They showed the characteristic cough and among them ten presented a grave form, both as regards the frequency and intensity of the attacks and in the general depression of the system. The duration of the illness was twelve days from the beginning of treatment, the average duration being thirty to forty days. All of the cases were cured in twelve to fifteen days by injections of two c.c. of ether every second day. The rapid recovery in all these cases was all the more remarkable, as the patients were poor working class children of feeble constitution and poor organic resistance. The treatment by injections of ether was particularly valuable, as it succeeded in cutting short an epidemic in an institution where the ages of the inmates rendered them eminently susceptible to infection.

Bronchomoniliasis.—Th. Joekes and R. H. Simpson (*Lancet,* July 21, 1923) state that bronchomoniliasis occurs more frequently than is suspected. Clinically, the disease presents no distinct entity. It occurs mostly in climates that are both hot and moist. The Monilia group are related to the Oïdia. Outside the body they are found widely distributed, but especially on fruit and dead leaves and wood. In the sputum they appear as round or oval Gram positive, yeastlike bodies, sometimes showing a double contour. Not infrequently tiny white particles, representing masses of growth, may be visible to the naked eye. In man, direct infection from case to case may occur, but more commonly bronchomoniliasis results from the inhalation of contaminated particles. Pulmonary infection may also occur by spread from a cutaneous source. In primary infections of the respiratory tract, the mouth and pharynx usually escape, but secondary infection from this source may occur in debilitated persons. Mixed infections, especially with the tubercle bacillus, are not uncommon. Clinically, all grades of severity are met with. Physical examination reveals signs of bronchitis or, perhaps, bronchopneumonia. In the more severe cases wasting is marked, and may be accompanied by all the signs and symptoms usually associated with pulmonary tuberculosis. The diagnosis may be difficult, and it depends upon the repeated demonstration of the fungus in the sputum. The specimens must be collected in sterile vessels and washed repeatedly before cultivation. The patient should gargle with sterile saline solution or with a dilute solution of potassium permanganate before expectorating. The administration of potassium iodide in large doses is effective therapy, although the tincture of iodine is perhaps more effective.

Experimental Studies of the Nasopharyngeal Secretions From Influenza Patients.—Peter K. Olitsky and F. L. Gates (*Journal of Experimental Medicine,* April, 1923) vaccinated fourteen volunteers with bacillus pneumosintes, at five to eight day intervals, giving three graded doses of heat killed cultures. Three of the volunteers were given a fourth and larger dose. Blood specimens were taken before and after vaccination for comparative agglutination tests. Only mild local reactions of a transitary nature were noted, and the constitutional reactions, consisting of headache, depression and generalized muscular pains, were also mild and transitory. Following vaccination there was a transitory leucocytosis and the appearance of specific agglutinins in the blood.

Varicella, Vaccine, Immunity.—Gustav Morawetz (*Wiener klinische Wochenschrift,* June 29, 1922) draws the following conclusions from observations on a large amount of clinical material: 1. In order to achieve general immunity, the appearance of antivirulent substances are necessary, in addition to the tendency to protection of the cells of the skin tissue. 2. Not only the epidermal cells, but also the cellular interstitial tissue of the internal organs must, in the event of an infection, be able to reproduce antibodies, to the protective activity of which the virulicide power of the blood should be chiefly attributed. 3. The immunity of the mucous membranes does not seem to run parallel with that of the external layer of the skin, but seems to be mainly dependent upon the appearance of antivirulent substances in the circulation. 4. The act of overcoming a smallpox infection calls forth an increased protective capacity in the cells of the internal organs in contradistinction to vaccination. The immunity acquired by the variola, therefore, protects more securely and for a longer time than vaccination against a spontaneous smallpox infection, against which a rapid appearance of virulicide substances in the circulation and in the mucous membranes must result from a promptly developing protective capacity in the internal organs. In this way the skin immunity must be lost sooner (smallpox inoculation with local result but without a subsequent general disease, positive vaccination). 5. Under certain conditions, especially under the influence of smallpox infection of the mother probably, a transient passive immunization of the infant may result during the first few weeks of life from transference of the maternal protective substances.

Differential Diagnostic Observations on Variola Vera, Modified Smallpox in Unvaccinated Persons and Varicella.—Tièche (*Schweizerische medizinische Wochenschrift,* May 3, 1923) designates the modified form of smallpox occurring in vaccinated individuals as varioloid and the primary modified smallpox occurring epidemically since 1921 in Switzerland as variola modificata. The great benignity of the disease and the frequently slight exanthem is charactertistic, so that there is great difficulty in differentiating it from varicella. However, there is no doubt that this is true smallpox, a variety of variola vera. Subsequent inoculations in unvaccinated individuals were always positive, whereas the pustular contents in varicella always gave a negative cutaneous reaction and a negative Paul reaction. The absence of prodromal fever and remittance of the fever during the spread of the exanthem are characteristic for varicella. The author lays great stress upon the distribution of the exanthem; even in these modified forms of smallpox there is the uniform regular development of the greater part of the efflorescences, especially the affection of the face and of the extremities, with very little on the chest and abdomen. Other very characteristic features are the firmness and hardness of the efflorescences, which cannot be wiped away like the varicella vesicles. The rosette forms are not characteristic.

CLINICAL MEDICINE.

Cholesterol Content of Blood in Anemia, and Its Relation to Splenic Function.—William MacAdam and Cecilia Shiskin (*Quarterly Journal of Medicine,* April, 1923) found that after splenectomy in acholuric jaundice and doubtless also in splenic anemia there is a gradual but very considerable increase in the total cholesterol content of the plasma and a progressive improvement in the blood count. However, the increase in the lipoids appears not to be related to any change in the corpuscles themselves. In the cases studied the abnormal fragility in hemolytic jaundice persisted three months after splenectomy, although the icteric tint and the urobilinuria disappeared within ten days of operation. The evidence pointing to a considerable increase in the cholesterol of the blood plasma after splenectomy in hemolytic jaundice seems conclusive, but the relationship of this hypercholesterolemia to the cessation of splenic function is quite undefined.

Complement Fixation Reaction as Applied to Leprosy.—Paul A. Lewis and Joseph D. Aronson (*Journal of Experimental Medicine, August,* 1923) found that the sera from thirty-nine cases of leprosy gave complement fixation reactions with all of the antigens used, which consisted of bacillus lepræ (Clegg), (Duval), and (Kedrowsky), bacillus tuberculosis, alcohol extract; Petroff's antigen, and cholesterol and acetone insoluble antigens (Wassermann reagents). The number of reactions with the tubercle bacillus or its products was actually higher than with any of the cultures having leprosy as a source. The reaction is apparently nonspecific. The property of multiple fixation may sufficiently characterize the disease to be of diagnostic significance, although judgment must be reserved for the present on this point. The most characteristic fixation given by the leprosy sera is that with bacillus lepræ (Clegg), used as antigen, either in the form of a bacterial emulsion or of an alcoholic extract of the dried culture. Antibody absorption may be demonstrated in the acidfast group if the absorbing bacteria are removed by filtration. Otherwise the resulting fluid is strongly anticomplementary. Leper serum is not deprived of the complement fixing body when so treated with either bacillus tuberculosis or bacillus lepræ (Clegg).

Utilization of Carbohydrate by Rats Deprived of Vitamine B.—H. A. Mattill (*Journal of Biological Chemistry,* April, 1923) describes a simple apparatus by which, in conjunction with a Haldane apparatus for gas analysis, respiratory quotients can be determined on small animals in twenty to forty minutes. Such determinations were made on rats on rations with and without vitamine B, which were fed carbohydrate in the form of cane sugar or glucose. Evidently vitamine B is not related to the metabolism of carbohydrate, since the quotients rose in both groups of animals, slightly less than those deprived of the vitamine, due probably to delayed absorption. Basal quotients were alike in both groups, nonfasting quotients slightly lower in the animals deprived of vitamines, this reflecting their semifasting state.

Blood Picture of Uncomplicated Pellagra.—John G. Huck (*Bulletin of the Johns Hopkins Hospital,* May, 1923) quotes from the literature on the blood picture in pellagrins to show that it abounds in contradictions. He then describes the blood picture in ten cases of pellagra at the height of the illness, in twenty cases during convalescence, and in five during the course of pellagra. In most instances the hemoglobin showed a slight decrease, the red blood cells showed a slight reduction; the color index was normal in all but six cases, in which it was slightly low. The leucocytes were in normal limits except in one case where the patient had a cold. The differential count was the most striking feature of the blood picture; when the symptoms are severe there is an increase in the lymphoid elements. With the subsidence of symptoms and in the convalescent stage, there is an increase in the polymorphonuclear eosinophiles. Eosinophilia indicates a favorable prognosis. The platelet counts are normal.

Quantitative Studies With Arsphenamine.—A. C. Kolls and J. B. Youmans (*Bulletin of the Johns Hopkins Hospital,* May, 1923) used the diazoreaction of Abelin, which was found to yield trustworthy results with arsphenamine containing blood specimens obtained either by the addition of the drug *in vitro,* or by drawing blood from animals or from man after intravenous injection. The method is also applicable to tissues, spinal fluid, and urine. An experiment is described in which a dog received disodium arsphenamine in doses of twenty mgm. to the kilo. The distribution and concentration of arsphenamine in the blood, spinal fluid, bladder urine, spleen, liver, lung, heart, kidney, pancreas, intestine, muscle and brain were determined by the method described. Old solutions gave reactions with very little less intensity than fresh arsphenamine. It was shown that oxyaminophenylarsenoxide gave the test as readily as the mother substance. This compound has long been reputed to be the first oxidation product.

Variations in the Threshold in Renal Glycosuria.—George Graham (*Quarterly Journal of Medicine,* April, 1923) describes four cases of renal glycosuria which apparently are links between frank renal glycosuria cases and normal individuals. No sugar is detectable in the urine when the patient fasts for a short while, but when carbohydrates are eaten, sugar is excreted in the urine. The sugar tolerance (the height to which the level of the blood sugar rises after a dose of sugar) is normal.

Metabolic Studies in Four Cases of Addison's Disease.—Kensuke Gyotoku and Mune Momose (*Mitteilungen aus der medizinischen Fakultät zu Tokyo,* Band XXX Heft 1) never found distinct hypoglycemia in spite of repeated examinations. Although the blood sugar content in one of two lethal cases showed a gradual reduction in connection with the aggravation of the general condition, it nevertheless remained absolutely normal in another case until shortly before death. Adrenalin is effective in patients with Addison's disease as well as in healthy persons. The authors found just as marked an alimentary hyperglycemia in cases of Addison's disease as in healthy individuals, consequently the assimilation capacity for carbohydrate in this disease is not particularly increased, as is generally assumed. In two investigations, the nitrogen balance in severe cases was negative, whereas in two other light cases it was positive. It is noteworthy that the balance for calcium was negative and positive for phosphorus in all of the cases, whereas the finding for magnesium were uncertain. In one case sodium chloride was distinctly increased, but in the other cases there was less administered than was excreted.

Conditions Determining the Transplantability of Tissues in the Brain.—James B. Murphy and Ernest Sturm (*Journal of Experimental Medicine,* August, 1923) found that when a mouse tumor graft (sarcoma) was implanted entirely in the brain substance of rats, it grew almost invariably with great rapidity. In practically every instance in which the implant failed to grow, examination showed it had come in contact with the ventricle. Of fifty rats receiving a graft of mouse sarcoma and an autograft of spleen, in only eight tumors developed, and practically without exception these were small. On the other hand, sixteen of twenty-one rats receiving tumor and homologous spleen graft sizable tumors developed. Immunized rats inoculated into the brain with homologous spleen and tumor grafts have considerable resistance, while immunized mice inoculated with tumor alone are almost completely lacking in a defensive reaction to tumor growth. Although the brain is without obvious power of resistance to implants of transplantable heteroplastic mouse tumors, yet grafts of spontaneous tumors fail to grow there even, as a rule, when tumor implanted and animal are of the same species.

NEW YORK, WEDNESDAY, DECEMBER 19, 1923

OBSTETRICS.

Postpartum Hemorrhage.—J. A. Kinnear (*Canadian Journal of Medicine and Surgery*, February, 1923) says that the prophylactic treatment is the most important. Postpartum hemorrhage is usually preventable. In its severe forms it seldom occurs in the practice of careful men. The patient should not be allowed to linger in labor until she is exhausted. Do not express the placenta until it is separated from the uterus, unless she is bleeding. Do not give any more anesthetic than necessary. This does not mean that we should forget the humanitarian side of our work and allow our patients to suffer unnecessarily, but that we should not permit familiarity with anesthetics to breed carelessness. Pituitary extract is a valuable remedy when properly used, but a most dangerous one when improperly used. After using much anesthetic, or giving pituitary extract, if the uterus has been overdistended with hydramnios or twins, ergot should be given hypodermically. If the placenta is still *in utero*, get the uterus to contract by massage and express the placenta by Credé's method. If you cannot express it, remove it manually. Then, with the closed fist in the uterus, and the other hand massaging the uterus, it will contract down on your hand and bleeding cease.

Relationship of Eclampsia to Other Toxemias of Pregnancy.—Gibbon FitzGibbon (*Irish Journal of Medical Science*, August, 1922) gives the following as the regular treatment of a toxemic patient in the Rotunda Hospital, Dublin: The patient is kept in bed. A full dose of purgative is given. If the bowels have not acted for some time enemata are given and repeated. If there is vomiting, enemata are continued, and at the end of twenty-four hours a purgative is invariably retained. Purgation is maintained. The patient is induced to drink as much water as possible, at least six pints, but preferably more, in the twenty-four hours. This treatment is continued until the symptoms have enormously abated, and the secretion of urine at least up to normal, with a moderate amount of albumin. The patient is then tried on a half pint of milk, and gradually brought up to a low diet, without meat. If she stands this she is allowed to go home, and attends the dispensary, with strict injunctions about diet; and is told to take a purgative every day to produce at least two movements. In a number of these cases the patients are near term and come into labor, of the others some carry on to term, and deliver themselves without further trouble. Some of the patients return with a renewal of marked symptoms. If the patient does not respond to treatment sufficiently to be tried on diet, or relapses as the result of diet, or if at any time the fetus is found to be dead, labor is induced.

Simultaneous, Combined Use of Mercuric Chloride and Arsphenamine in Puerperal Sepsis.—Hans Kiehne (*Zentralblatt für Gynäkologie*, March 17, 1923) states that the combined mercuric chloride and arsphenamine injections gave good results in puerperal sepsis and better results than such colloidal silver preparations as collargol. He considers this form of treatment, just like every other form, as unsuitable in pronounced peritonitis and in those cases that are subjected to treatment too late and where the patient's powers of resistance are exhausted. Furtheremore, this form of treatment will frequently fail so long as placental remains are left behind in the uterus. Therefore the conclusion is drawn that these remains should always be removed wherever possible. The author dissolves 0.3 grams of neoarsphenamine in five or six c. c. of tap water and adds two c. c. of a one per cent. solution of mercuric chloride and this mixture is injected intravenously. A second injection may be given after two or three days. As many as five injections may have to be given at progressively longer intervals.

Forceps Procedure With the New Kielland Obstetrical Forceps.—E. Frey (*Schweizerische medizinishe Wochenschrift*, March 29, 1923) mentions the advantages of the Kielland forceps for the general practitioner, as follows: 1. It can be applied in the biparietal diameter. 2. It can be applied effectively to the head in both the high and low transverse position of the head in the pelvis. 3. Thanks to the sliding lock an accurate adaptation of the forceps to the head is possible and a slipping of the forceps is prevented. 4. As a result, there is no danger of compressing the fifth lumbar nerve and no resulting traumatic neuritis in the peroneal region during the puerperium. On the strength of these advantages, the Kielland forceps is recommended to the general practitioner under the classical indications, which are as follows: 1. The forceps operation is indicated only in conditions threatening to the mother or child, in so far as the simple Cristeller procedure is futile. 2. The following prerequisite conditions must be fulfilled: a, the child must be alive and viable; b, the cervix must be completely dilated; c, the head must have passed the pelvic inlet with its greatest periphery; d, the promontory must be no longer palpable; e, there must be no marked deflexion as long as the head is still in the pelvic cavity; and f, the pelvic outlet must not be constricted.

Therapeutic effect of bacillus acidophilus milk. Ten illustrations 742

Tubal abortion. Three illustrations 592

Tumors of the bladder, treatment of. Seven illustrations 262

Unilateral bifid ureter with duplicate ureter and ureterocele on opposite side. Seven illustrations 302

Ureteral stricture in female. Four illustrations.565

Vincent's infection of mouth. Five illustrations.150

Walæus, Johannes, work of. One illustration..638

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Thousands of busy practitioners turn to Gray's Glycerine Tonic Comp. whenever a restorative or reconstructive is needed, because their experience has shown them that it can be relied on to produce the results they seek.

Dysmenorrhea

is one of the most common and intractable affections that tax the skill of the practitioner. Fortunately, in

Hyperol

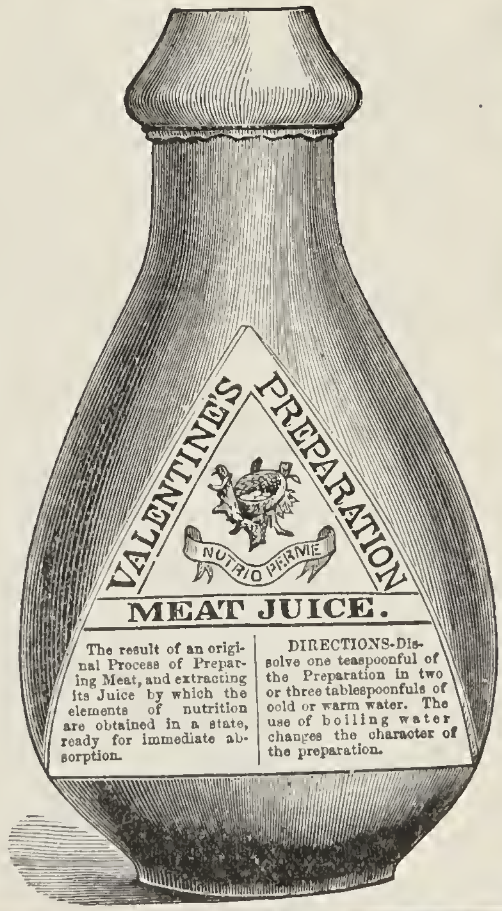
the practicing physician has a remedy that, owing its beneficial action to its regulation of the utero-ovarian circulation, promptly reduces the local congestion and thus effects an early relief from pain. Not the least, therefore, of the notable advantages of Hyperol, is the way it obviates, in the great majority of cases, any necessity for opiates or narcotic drugs, with their all too evident dangers.

But it is through its restoration of normal functions of the uterus and ovaries that Hyperol accomplishes its greatest benefits, for it thus enables medical men to produce results in **amenorrhea, dysmenorrhea, subinvolution and kindred ills** that are possible with few other remedies.

135 Christopher St. **The Purdue Frederick Co.** **New York**

Valentine's Meat-Juice

In **Diarrhoea, Dysentery** and **Cholera Infantum,** in the **Wasting** and **Febrile Diseases** of **Children,** and in the treatment of **Weak Babies,** the **Ease** of **Assimilation** and **Power** of **Valentine's Meat-Juice** to **Restore** and **Strengthen** has been demonstrated in Hospitals for Children.



VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Diseases of Children.

W. T. Watt, M. D., *Director Imperial Medical College, Tientsin, China:* "In cases of Infantile Diarrhœa, which weakens and debilitates a child rapidly, I have found VALENTINE'S MEAT-JUICE a great stimulant and quick restorative of vitality. Three years ago when an epidemic broke out in Tientsin, I ordered my staff to try your MEAT-JUICE, which justified all expectations, having been satisfactory to patients and physicians alike."

Dr. Calatraveno, *Late Physician of the Children's Hospital, Madrid, Spain:* "I have employed VALENTINE'S MEAT-JUICE most successfully in cases of convalescence from infectious diseases, and it is especially beneficial for children suffering from urinary weakness caused by extreme debility, as in every case it acted remarkably in restoring their strength with notable rapidity."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,
Richmond, Virginia, U. S. A.

MISCELLANY.

Management of Early Cases of Chronic Infectious Arthritis.—Russell L. Cecil (*Medical Clinics of North America*, November, 1922) states that every case of arthritis requires individualization in treatment. An accurate history is most important in determining the etiology, and the history should include the inquiry concerning attacks of tonsillitis, alveolar abscesses, sore throat, colds, genitourinary diseases, diseases of the gastrointestinal tract, colitis, gallstones and appendicitis. The oral cavity and the extremities must be examined with particular care. Cultures should be made from the prostatic secretion. We must determine whether the joint itself or the surrounding muscles and tendons are involved, whether the inflammation is periarticular, osseous or cartilaginous, also the degree of ankylosis, and whether it is fibrous or bony. The laboratory tests should include a Wassermann reaction and the amount of blood, sugar and uric acid in the blood. The röntgenogram indicates the extent of the lesion and the prognosis. Cultures should be taken from all possible foci of infection.

The treatment depends upon whether the condition is one of active infection or one in which the infection has already been overcome and is followed by secondary fibrous changes. In active cases all possible sources of infection should be eradicated. Heat, in the form of hot baths, baking, electric pads, sun baths, etc., is most important. Massage must be used with great caution in active cases. A low carbohydrate diet is important. The bowels should be kept active with laxatives if necessary and high colonic irrigations are valuable in the gastrointestinal cases. Salicylates are used occasionally, but potassium iodide or hydriodic acid is used more frequently. In the postinfectious stage foci of infection should be removed and heat and active and passive exercises are important. Arthritis is a selflimiting disease, and many cases recover without any treatment.

Researches on Yellow Fever. Comparative Etiological, Pathological, and Epidemiological Considerations; Prevention and Treatment.—Hideyo Noguchi (*Lancet*, June 17, 1922) states that the morphological features of the Leptospira icteroides are almost indistinguishable from those of Leptospira icterohemorrhagiæ or Leptospira hebdomadis and other nonpathogenic varieties of leptospira, but yet the pathogenic varieties are by no means identical. The icteroides is predominantly icteronephritic, with a marked tendency to produce fatty degeneration of the parenchymatous cells of the liver and kidney; the hemorrhage into the mucous membranes is more marked in experimental infections than in the experimental infectious jaundice. In the hebdomadis infection there is only a slight tendency to jaundice or none at all; in the human disease, also, the differences are chiefly of degree. While a typical case of yellow fever is not readily confused with typical infectious jaundice, there are many borderline cases in which only epidemiological differences can decide the diagnosis. Infectious jaundice usually shows a slight leucocytosis, whereas in yellow fever the leucocytes are but slightly increased, the differential counts in the two diseases being similar. The two diseases are produced by two distinct but closely related species of leptospira, just as yaws, syphilis, and rabbit venereal disease are three different diseases caused by three morphologically indistinguishable but distinct species of treponema.

The fatty degeneration of the liver and kidney in human yellow fever and in experimental animals show that the Leptospira icteroides is the cause of yellow fever. Animals inoculated with unbroken series of passages of the Leptospira icteroides show less jaundice, the liver is less fatty, the kidneys and other tissues are more hemorrhagic and death occurs from leptospiremia. The picture in such animals is different from that found in animals inoculated with a strain freshly isolated from human cases or one passed through a few generations on the leptospira medium of the mosquito. If yellow fever was transmitted directly from man to man without an intermediary host in an unbroken series, the clinical picture might be different. Guineapigs, puppies and marmosets are inoculated only with difficulty, and practically they are never sources of danger to the community.

Wherever an antistegomyia campaign is unavailable, or when a case of yellow fever has occurred in a community, the use of immune serum is indicated. If given in the incubation period the serum prevents the development of infection. Vaccinated persons are perhaps as susceptible as the unvaccinated during the first ten or fifteen days following the last injection; after that time the protection becomes effective. Early treatment reduced the mortality from fifty-two per cent. to thirteen per cent., and it also alleviates the subjective and objective symptoms.

The Blood Transfusion Method in the Prevention of Quinine Intoxication.—E. Keramopoulos (*Presse médicale*, June 24, 1922) comments on the relative inefficacy of quinine substances, and reports the case of a female malaria patient of thirty-seven years in whom oral or intramuscular administration of quinine always caused dyspnea, faintness, tachycardia and urticaria. Substitution of intravenous injections of novarsenobenzol and collargol for the quinine resulted in similar untoward symptoms, except that urticaria was absent. Besredka's method of specific tachyphylaxis by repeated injections of small amounts of quinine, as well as nonspecific prophylaxis with sodium carbonate, were next tried, but without success. A series of blood transfusions was then begun. Every two or three days twenty mils of blood was collected aseptically from the bend of the elbow of the patient's daughter in a syringe containing two mils of four per cent. sodium citrate solution, and immediately injected into the patient's vein. Merely a slight febrile reaction followed these injections on some occasions, but soon the patient's blood and body weight began to show distinct improvement, and furthermore, when a 0.1 gram tablet of quinine hydrochloride was administered, it was well tolerated. Later, the patient daily, for a considerable time, took one gram of quinine divided into two doses, without exhibiting the least sign of intolerance. The relief from quinine intoxication in this case is definitely ascribed by the author to the treatment by repeated blood transfusions.

Constipation in Young Girls and Women—

especially those who spend much time indoors engaged in sedentary pursuits—is almost invariably attended by a retention of waste and toxic substances. Sooner or later these make their way from the bowel into the general system and give rise to a host of autotoxic ills.

Correction of this condition is imperative, and, the safest, simplest and most effective remedy for the purpose is

INTEROL

a pure mineral oil of the proper density and viscosity to assure satisfactory lubrication of the intestinal canal, and thus relieve and correct bowel inactivity without the usual disagreeable effects of cathartics as commonly employed.

Besides lubricating the canal, INTEROL renders the feces soft and plastic, thereby promoting their easy passage and evacuation with gratifying freedom from discomfort and distress.

It would indeed be difficult to suggest any more serviceable and agreeable medium for the correction of constipation, with its attending autotoxemic conditions, than INTEROL.

Sample and Interol brochure on request.

Allied Drug and Chemical Corporation
2413 Third Ave., New York City

MANUFACTURERS OF ORASEPTINE—Internal and External Antiseptic, Wash, Spray and Douche.
ADACCO SALT—Effervescent Saline Laxative and Uric Acid Solvent.
VELOGEN—"The Doctor's Hand-maid and Household Emollient."

Directions:

To relieve the constipation of young girls and women, give two to four teaspoonfuls of INTEROL morning and night, increasing or decreasing the quantity as conditions require. As the bowels yield to the action of INTEROL, gradually cut down the dose to the least amount that—taken at bedtime—will assure a daily evacuation.

VITTEL

—VOSGES, FRANCE

VITTEL
GRANDE SOURCE

THE mineral water of VITTEL GRANDE SOURCE recognized as of Public Utility by the French Government is refreshing, light, most agreeable to drink, essentially diuretic, and so necessary against all tendencies of arthritism: **rheumatism, gout, gravel, arteriosclerosis, high blood pressure, diabetes.** It is the surest antidote of **uric acid,** the great poison of the present generation.

Six sample quart bottles of **VITTEL GRANDE SOURCE** will be sent **Free** on request of any doctor. : :

Glucose and Blood Transfusion.—Dupuy de Frenelle (*Bulletin médical*, April 14, 1923) finds blood grouping unnecessary where blood to be transfused is diluted with glucose and commends this procedure to the practitioner in cases where the otherwise necessary and time consuming precautions cannot be taken. An intravenous injection of either a 4.7 or ten per cent. solution of chemically pure glucose at a temperature of 38° C. is slowly given from a suitable receptacle, and during the process the elbow of the donor is held above the receptacle, a vein punctured, and two hundred grams of his blood allowed to flow into the solution. This amount of blood can be given in from five hundred to one thousand cubic centimetres of the glucose solution without blood grouping. Tests showed that the 4.7 per cent. solution kept the blood from clotting for half an hour and the ten per cent. solution for over an hour, when one part of blood was mixed with four parts of glucose solution. Fifteen patients were saved by this procedure who, it is believed, would have succumbed had the usual blood grouping been resorted to.

Rapid Closure of Incisions With the Loop Stitch.—C. Lasserre (*Journal de médecine de Bordeaux*, April 10, 1923) folds six to ten pieces of suture material at their middle, wraps the ends in a piece of gauze so that merely the loops project, and holds the gauze in the left hand. With the right hand a Reverdin needle is passed through the margins of the wound at suitable intervals, each time drawing back a loop of suture material with it. When a sufficient number of loops has been inserted, the needle and excess of suture material are laid aside, and one end of each suture passed through the corresponding loop. Upon pulling on both ends of the suture, the wound margins are automatically drawn in exact apposition and the suture is tied with a plain knot. The procedure gives precise coaptation without loss of time and permits the use of a loop stitch without assistance from another person.

Pollen and Hay Fever. A Regional Problem.—W. V. Mullin (*Colorado Medicine*, April, 1923) thus summarizes his paper: 1. Hay fever is caused almost exclusively by plants whose pollen is sufficiently light and abundant to be distributed widely through the air. 2. Many of these plants are limited to certain sections of the country, or are unevenly distributed, and in consequence, the etiology of hay fever becomes largely a regional problem. 3. Much of the failure in pollen extract therapy is due to an insufficient knowledge of the botany of plants with wind borne pollen. 4. If the best results are to be obtained, a survey of such plants should be made by competent authorities for each locality, to determine the species present, their relative abundance and pollinating time. 5. The individual case should be treated with a full knowledge of the significant plant life in the region in which his hay fever develops. 6. Diagnosis is simplified by a thorough study of the history of each case in connection with an adequate local pollen survey, including the use of pollen plates. 7. Treatment with pollens gathered in the region in which the attacks occur is always advisable and often essential. 8. Treatment during attacks presents many difficulties, but promises increasingly good results.

Capillary Microscopical Investigations.—G. Linzenmeier (*Zentralblatt für Gynäkologie*, June 24, 1922) does not believe in the theory that angiospasms are the sole cause of capillary stasis. As this stasis is frequently found in eclampsia, he investigated the pathogenesis of eclampsia and the question whether the stasis observed in eclampsia resulted from it and also the phenomena of the expression of a vascular spasm. He repeatedly observed that the stases in adjacent capillaries occur independently of one another, occurring preferably in thin capillaries, which finding contradicts the Hinselmann theory that the stases are due to obstruction of the arterial supply of the capillary coils. This theory is also contradicted by the fact that the blood pressure in febrile and septic conditions, in which stasis occurs more often than in pregnancy and eclampsia, is always diminished and the vasomotor system is frequently paralyzed; spasms often occur, however.

It has been shown that the granular appearance of the blood stream is due to agglutination of the erythrocytes, which phenomenon occurs in every case where a rapid sedimentation of the erythrocytes occurs as soon as the rapidity of the circulation is diminished. The author's experiments showed a striking parallelism between the rapidity of the sedimentation of the erythrocytes and the picture observed in the capillary circulation. Persons who show a slow sinking rate also show many stases, and those showing rapid sedimentation of the erythrocytes also show a granular circulation and proportionately many stases. There is undoubtedly a relationship between the instability of the suspension of the erythrocytes and the changed capillary circulation. Another factor favoring the clumping of the erythrocytes is the slowing of the current in the capillaries and here the increase and the marked lowering of the blood pressure act identically; a rise of blood pressure results from the resistance in the peripheral vessels; the diameter of the lumen of the vessel affected is diminished and the blood supply is therefore lessened and a slowing up of the capillary circulation results. In both eclampsia and in septic diseases the capillary circulation is slowed from various causes and this, as a result of the existing increased rapidity of sedimentation of the erythrocytes, favors the clumping of the erythrocytes and with it the formation of stases.

Salivary Glands in Carcinoma.—L. S. Dudgeon and Philip H. Mitchiner (*Lancet*, September 9, 1922) find that in the vast majority of cases of carcinoma of the tongue and floor of the mouth, the salivary glands are not the seat of carcinoma. In nearly every case the changes present in these glands are of a chronic inflammatory nature, somewhat analogous to the changes observed in the pancreas in chronic pancreatitis and apparently due to infection from the mouth along the ducts; other cases show no microscopic changes. The lymph nodes in this area show malignant changes in only 27.3 per cent. of early and fifty per cent. of late cases, though inflammation is always present. It would appear, therefore, in certain cases with early carcinoma of the tongue, to be justifiable to leave the submaxillary area untouched at the operation, although clinical experience teaches that the risk of the subsequent appearance of metastases is very great.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Thousands of busy practitioners turn to Gray's Glycerine Tonic Comp. whenever a restorative or reconstructive is needed, because their experience has shown them that it can be relied on to produce the results they seek.

Dysmenorrhea

is one of the most common and intractable affections that tax the skill of the practitioner. Fortunately, in

Hyperol

the practicing physician has a remedy that, owing its beneficial action to its regulation of the utero-ovarian circulation, promptly reduces the local congestion and thus effects an early relief from pain. Not the least, therefore, of the notable advantages of Hyperol, is the way it obviates, in the great majority of cases, any necessity for opiates or narcotic drugs, with their all too evident dangers.

But it is through its restoration of normal functions of the uterus and ovaries that Hyperol accomplishes its greatest benefits, for it thus enables medical men to produce results in **amenorrhea, dysmenorrhea, subinvolution and kindred** ills that are possible with few other remedies.

Valentine's Meat-Juice

In **Typhoid, Gastric** and **Other Fevers,** where it is **Essential** to **Sustain** the **Patient** without **Irritating** the **Weakened Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening** when **Other Food Fails.**

J. R. Wood, M. D., *Physician Sheltering Arms Hospital, Paint Creek, W. Va., U. S. A.:* "I have been using VALENTINE'S MEAT-JUICE in the treatment of Typhoid Fever cases in the Sheltering Arms Hospital, for the last two or three weeks, with the most gratifying results both to the patient and physician. I consider it the best preparation of animal food I have ever seen, in fact, the only one I have ever had any success with."

Dr. Genevaix, *Assistant Surgeon-Major, First Class, Hotel Dieu, Creusot, France:* "The patients to whom I have given the excellent preparation, VALENTINE'S MEAT-JUICE, have found their general condition rapidly improved by it, and in the convalescence from continued Fever (Typhoid and Para-Typhoid) it gives the best results."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY.

The Cancer Patient.—Ernest Frederick (*Canadian Practitioner*, January, 1923) advises the insistence upon a gradual increase of muscular activity. Forbid the constant use of the motor car, encourage golf, walking, gardening, woodchopping, or calisthenics. If the patient is unable to do these things, urge the use of "resistance exercises, in which the patient, while lying or sitting still, contracts vigorously a set of flexors resisting their action by a simultaneous contraction of their opposing extensors." Thus the use of all the muscles in the body can be brought about. This is the main idea in a "system" well advertised and sold for a hundred dollars. Another necessity is to cut down and alter the diet, not as a temporary measure, but as a continuous habit of life. He urges the following intensive diet: Three pints of vegetable juice daily, one and a half pints of fruit juice daily, raw vegetables and fruits *ad libitum*, ground or scraped if necessary to make them digestible, and so mixed as to make them palatable, stewed and cooked vegetables and fruits, sugars, starches and syrups, cereals, bread and cakes, pies and jellies enough to fill out the day's need. Forbid proteids. Psychical and physical benefit results from taking a mild cathartic and diuretic for months. Thyroid glands and arsenic have proved of value, the former probably by stimulating general metabolism, the latter by preventing overrapid breaking down of the nitrogen from the protein molecules.

The Theory of the Stimulation of Turning on the Semicircular Canals. — Fritz Rohrer (*Schweizer medizinische Wochenschrift*, July 6, 1922) conducted systematic experiments on guineapigs and on models which resembled the mechanical relationships of the semicircular canals, in which the resultant nystagmus was observed after varying the direction, rapidity and time of turning. He found: 1. That the duration of the resultant nystagmus increases with the rapidity, beginning at a certain threshold value (in the guineapig) of three to four seconds, at first rapidly and then more slowly. The optimal duration of turning is independent of the rapidity. Turning toward the left results in a longer duration of the nystagmus than does turning to the right, this being the result of a deeper position of the threshold turning rapidly than when the turning is toward the left; the same relationship holds in regard to the number of oscillations of the subsequent nystagmus. 2. Variations in the length of the turning radius of 1.4 to 27.4 cm. produced no increase, but a slight decrease of the reflex phenomena produced by the labyrinth, and therefore a synergism of the fleeting powers is unlikely as a result of stimulating the semicircular canals. 3. Turning experiments on models mechanically resembling the semicircular canals show a similar dependence of the duration of the subsequent nystagmus, produced by rotatory tardiness upon the variable factors of the turning procedure; it is therefore likely that the cause of this variation in the semicircular canals must be sought in the peripheral end organs and not in the relationships of the central apparatus. 4. Proceeding from the theory of the current processes and the theory of the elastic swayings, the mechanical processes in the semicircular canals in relation to the turning process may be treated according to a fixed formula.

Periodical Alkalemia with Alkalosis in the Adult.—With the aid of investigations on the blood and alveolar air, William MacAdam and John Gordon (*Lancet*, September 9, 1922) show that during the attacks of sickness there is a low hydrogen ion concentration of the blood, a low carbon dioxide tension of the alveolar air, and a high carbon dioxide combining power of the blood plasma—a condition of alkalemia with alkalosis. The treatment with large doses of tenth normal hydrochloric acid produced satisfactory results; the administration of ammonium chloride was unsuccessful, owing to the induction of vomiting. A clinical association of acetonuria with a condition of alkalemia was thus demonstrated. These findings may afford an explanation of some of the unsatisfactory results following the administration of large doses of alkalies in certain conditions of acetonemia, while some of those metabolic disturbances (certain types of toxemia of pregnancy), in which a low ammonium index is associated with severe clinical symptoms may be due to the swing of the acid base balance of the blood to the alkaline side.

Anaphylaxis Among Bacteria.—F. Arloing and L. Thévenot (*Paris médical*, June 24, 1922), recalling Richet's investigations on habituation and anaphylaxis as displayed in the lactic ferment, tested in Bacillus diphtheriæ, Bacillus pyocyaneus, Bacillus subtilis, and Bacillus prodigiosus the anaphylactic effects produced by a sudden change in the amount of serum added to their cultures. The organisms were first sensitized by culture for five days in ordinary bouillon to which were added in different series of tests, four, forty, or eighty per thousand of normal horse serum. The anaphylactic shock was then induced by transferring the germs directly for eighteen hours into bouillon with two hundred per thousand of serum. The effects of the shock were verified in plain bouillon and agar. The general biologic characteristics of the organisms were found to have been altered by the procedure. The culture films and pigmentation were strikingly changed and the virulence of the diphtheria bacillus was reduced. The morphological features and staining properties were, however, not influenced. The changes observed are regarded as manifestations of anaphylaxis in the bacteria referred to.

A New Hydrostatic Bag for the Induction of Labor.—G. H. Lee (*American Journal of Obstetrics and Gynecology*, June, 1922) describes a bag designed to combine the advantages of the Barnes, Voorhees, and Champetier de Ribes bags while eliminating their objectionable features. It comprises a globular portion intended to rest in the vagina just outside the cervix, a constricted portion which fits in the cervical canal and when distended dilates the cervix, and an enlarged, conical portion which is placed in the lower uterine zone and supplies an efficient foreign body to excite uterine contraction. Nothing protrudes from the vagina except the attached rubber tube, which is one centimetre in diameter. The bag is made of fairly heavy soft rubber, and can be folded within the grasp of a uterine dressing forceps so that it will pass through a cervix admitting the index finger. In appropriate cases a weight can be attached to the rubber tube.

Many Babies Die of Summer Complaint—

Breast Milk Might Have Saved These Lives

Every physician knows the importance of breast-feeding as a safeguard in the prevention of gastro-intestinal disturbances.

This information should be convincingly brought to the attention of every mother.

The physician also knows that where breast milk is not available—a properly modified, clean, nutritious substitute should be selected.

For the average normal baby, Eagle Brand milk (which is made from pure, fresh, full-cream cows' milk) is a clean, nutritious food.

This product, because it is clean and easily digested, has been used with good results in gastro-intestinal disturbances. No milk-borne epidemics have ever been traceable to Eagle Brand milk.

Pneumaturia.—Hermann Walthard (*Schweizerische medizinische Wochenschrift,* August 17, 1922) finds that laboratory investigations unquestionably show that the gas formation must be attributed to the bacterial decomposition of albuminous substances. The formation of the gas depends, not upon the amount of the albumin present, but apparently, more on the qualitative changes of the albumin. It is also possible that with the onset of convalescence, the albuminous substances, which at the fastigium of the disease at the time of the pneumaturia are excreted in the bladder unoxidized, are again retained in the body and decomposed in the bladder by the bacterial splitting and gas formation. A considerable amount of gas may be expelled even though the Esbach test shows no more than one fortieth of one per cent. of albumin present. The gas formation depends upon the nutrition and the digestion of the patient. The bacterial activity depends upon the action of the disinfections introduced by the mouth and the urethra, the urinary reaction, the changes in the urinary colloids and on the patient's resistance; other factors are the viability of the gas producing germs, their injury from autogenous metabolic products, and the variations of the gas forming capacity in the various bacterial generations. The prognosis in regard to life is not bad in pneumaturia arising from urine containing sugar or albumin. The decisive factor is the basic disease, of which the pneumaturia is after all only a symptom, namely cystitis, of which the causes and secondary condition are urinary retention in urethral stricture and prostatic hypertrophy, obstipation, diabetes, nephritis, appendicitis, adnexal diseases, etc. Alkalinization of the urine is useless and only an antidiabetic diet has been successful in eliminating the gas through the disappearance of the sugar; in those cases without sugar, even the antidiabetic diet failed. Autovaccines and salvarsan preparations may be useful.

Thermotherapy.—B. S. Price (*American Journal of Electrotherapeutics and Radiology,* January, 1922) summarizes as follows:

1. The unnecessary confusion existing with regard to the recognized distinguishing features and indications of the different forms of thermotherapy should be corrected as much unnecessary harm results from it. At the same time many lives are being destroyed through the lack of fulfilment of the possibilities.

2. Careless nomenclature used in the expression of the various forms of thermotherapy indicates its haphazard use and in the minds of many a confused and unrecognized conception of the distinguishing features. Heat brings about opposite results under different conditions, therefore definition is necessary. Human bakes do not exist in civilized communities.

3. The present degree of knowledge with regard to thermotherapy largely limits its application in therapeutics to the effects produced from the accompanying qualities of the modality rather than from the production of heat within the tissues except in the case of diathermy. Heat obtained from such active sources as radiation and electrical currents is accompanied in its effects by those of molecular massage and under high temperature, the initial stimulation more rapidly passes into depression than in the case of convective heat of high degree.

4. The different forms of thermotherapy, largely dependent upon their associated features, fill wholly different indications. Further, the results obtained vary widely even to the degree of antagonism dependent upon sudden exposure to high temperature or prolonged exposure to a low temperature and upon the mental and physical condition under which the patient is placed.

5. The significance of catabolic elimination requires more conscientious study than is generally recognized.

6. The oven bath properly given is a cellular waste eliminant and as such fills an entirely different indication from any other form of heat. It would seem to act mainly through the adrenosympathetic system. Oven bath stimulation is distinctly chemical in its last analysis of elimination and in no sense one of perspiration. Whereas other forms of heat may have a more marked influence upon metabolism under certain conditions, never do they markedly influence elimination. The oven bath is indicated wherever there is subelimination of toxic matters from the tissues, whether in the course of protein metabolism, as in nephritis, certain types of neuritis, rheumatism, etc., or in acidosis or other toxic conditions. It is also a valuable circulatory stimulant in these cases.

7. Cardiac incompetency is not a contraindication to the oven bath properly given.

8. In the use of superheated dry air as with other methods of modifying the circulation, it is important to maintain the circulatory changes thus produced until restored by Nature. Hence, the horizontal position is essential, and air cooling, as well as water cooling under improper temperatures must be avoided. Air cooling is impossible of regulation. Water regulation is possible.

9. The state of abeyance under which the cardiovascular control is placed for a few hours as a result of the oven bath is followed by marked improvement in its tone over that preceding the treatment. This is evidenced in functional hypotension cases.

10. There is necessity for discrimination and proper combination of measures in this as in all forms of therapy.

Treatment of Herpes Zoster.—Poirot-Delpech (*Paris médical,* March 10, 1923) recommends the local application of a solution of picric acid crystals, five grams, in ether and alcohol, of each fifty grams. The solution should on no account be brought near an open flame, and dressings should not be burned. The lesions are lightly treated with the solution on alternate days and a layer of cotton then applied. Internally, one or two grams of antipyrine a day are given, according to the severity of the pain. Under this treatment six out of eight patients recovered in three to six days, the other two requiring nine and twelve days, respectively.

Galvanopalpation and X Rays.—Max Kahane (*Wiener klinische Wochenschrift,* August 17 and 24, 1922) compares the results of the two methods of examination. Galvanopalpation serves to supplement the x ray findings. In diseases of the skin and the muscles, for example, the galvanopalpation has the advantage over röntgenography, whereas diseases of the bones belong to the domain of röntgen diagnosis. In the examination of other organs both methods of examination should be combined.

MISCELLANY.

Röntgen Ray Therapy of Tuberculosis of the Skin.—Richard Volk (*Wiener klinische Wochenschrift*, January 18, 1923) believes that röntgentherapy is dispensable in tuberculids. In erythema nodosum the results are good; they are just as good in the verrucous and ulcerated forms of lupus vulgaris. Moderate doses are preferable in these cases. Residual nodules should be extirpated with Finsen or Kromayer irradiation. Lupus of the mucous membranes, particularly lupus of the nose and lips, also react well to röntgenotherapy, but lupus of the larynx does not react so well. The torpid form of lupus erythematodes is also suitable for röntgentherapy, especially in chronic cases, even though the therapeutic results are determined with difficulty. The effects from röntgentherapy of lupus cannot be increased with injections of eosin or iodin. On the other hand, Volk is in favor of the preliminary treatment with strong pyrogallol salves and also with Unna's pepsin salve with only three to five per cent. pyrogallol (reduction of the toxicity). Röntgentherapy should be instituted as long as the lupus has not as yet ulcerated. It is possible that the danger of lupus carcinoma is somewhat greater after röntgentherapy than otherwise, but this may always be attributed to improper doses.

Variations of Vagosympathetic Tone in Serum Disease and Infectious Disorders.—Tinel, Santenoise and Laurent (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* March 29, 1923) depend on the oculocardiac reflex as the criterion of vagosympathetic balance in any given case. They enunciate the general law that hypervagotonia promotes rapid, violent and serious anaphylactic or anaphylactoid reactions as well as selective nervous intoxications, whereas hypovagotonia or sympatheticotonia afford the conditions most unfavorable to such effects and bring about a nonsusceptibility to them. Variations in both anaphylactic reactions and toxic or drug effects at different times are thus explainable on the basis of variations in the preëxisting neurovegetative balance. Anaphylactic shock is itself, however, a most powerful modifier of vagosympathetic balance, at first leading to a sudden, brief accentuation of the preëxisting state, then a more or less complete and lasting reversal of conditions. Thus, in a vagotonic subject any sort of anaphylactic shock soon leads to a sympatheticotonic state in the presence of which no further shock can occur. Most of the nonspecific antianaphylactic procedures appear to act in this way. On the other hand, in a sympatheticotonic subject there may appear secondarily a state of vagotonia during which the individual becomes susceptible either to a fresh shock or to persistent action of the injected material. This accounts, no doubt, for the appearance in sympatheticotonics of unexpected, always delayed and attenuated, reactions. Subcutaneous injection of horse serum in the ordinary moderate vagotonic generally leads on the second day, as the local erythema at the site of injection appears, to a lessening of the oculocardiac reflex, which may be abolished or even reversed. About the fourth or fifth day, when the local erythema has disappeared, there is a temporary return of the reflex, indicating a phase of hypervagotonia preceding the general urticaria. Then the reflex becomes reversed again through a period of two or three days of definite sympatheticotonia, which persists throughout the duration of the urticaria, and then recedes into the normal vagotonic state. In the occasional patients who are sympatheticotonic previous to the serum injection, the latter is followed merely by a slow passage into moderate vagotonia before the local erythema appears. This erythema is, as a matter of fact, inconstant, or at least delayed and greatly attenuated. There is then a gradual return to the preëxisting sympatheticotonia, and the urticaria is generally wanting or is extremely evanescent. In twenty-six cases of measles there was noted a hypovagotonia or sympatheticotonia reaching its acme at the height of the measles eruption and passing off as the eruption faded. Laurent had seen a similar condition in syphilitic roseola and in toxic or drug rashes. In pneumonia, broncho-pneumonia and typhoid fever there is a marked hypervagotonia as the temperature rises, followed by a more or less stable sympatheticotonia which persists until defervescence. Scarlet fever, however, reacts differently, showing in some instances a persistent hypervagotonia and in others irregular alternations of vago and sympatheticotonia. These alternations generally correspond with changes in blood pressure, the stages of hypervagotonia occurring along with sharp drops in the pressure. The case with the most pronounced hypervagotonia was one of severe scarlet fever with evidences of adrenal insufficiency, viz., blood pressure 95 mm. Hg, cyanosis of the limbs, extreme weakness, livid eruption at the knees and elbows, and a broad white line phenomenon, with complete disappearance of the scarlet rash in an area four or five centimetres wide. The authors suspect adrenal insufficiency with impaired sympathetic tone, giving free play to the opposed parasympathetic, to be a factor in the paradoxic hypervagotonia of scarlet fever. Some as yet unreported investigations have shown the importance of the endocrine glands in the regulation of vagosympathetic tone.

Experimental Inoculation of Human Throats With Virulent Diphtheria Bacilli.—C. G. Guthrie, B. C. Marshall, and W. L. Moss (*Bulletin of the Johns Hopkins Hospital,* December, 1921) used for this work inoculations of a virulent diphtheria bacillus obtained from the throat of a healthy carrier, obtaining from the investigation the following results: The carrier state was produced in seven of eight individuals, the probable duration varying from thirty-three to fifty-five days plus. The effect of diphtheria antitoxin in preventing the colonization of the organisms introduced was not complete or striking, and it is believed that it probably had no influence whatever in preventing the development of the carrier state. Such organisms are capable of producing clinical diphtheria, and when isolated in pure culture from the human throat after a prolonged sojourn there, they showed no alteration in morphology or in their staining or cultural characteristics. The authors conclude that the guineapig test is a reliable index of the inherent ability of diphtheria bacilli to cause clinical diphtheria in susceptible human beings, and the Schick test is a reliable index of the presence or absence of antitoxic immunity against diphtheria.

Sluggish Bowel Action in Childhood

is usually due to errors in feeding. Subjecting these fundamentals to the customary careful correction,

INTEROL

may be administered coincidentally to relieve the immediate condition.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

Sample and Interol brochure on request.

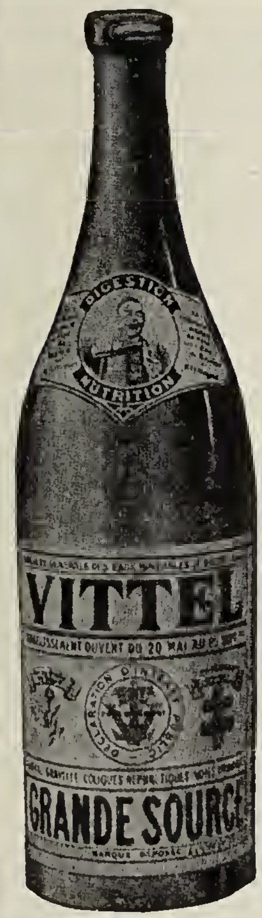
VITTEL

—VOSGES, FRANCE



THE mineral water of VITTEL GRANDE SOURCE recognized as of Public Utility by the French Government is refreshing, light, most agreeable to drink, essentially diuretic, and so necessary against all tendencies of arthritism: **rheumatism, gout, gravel, arteriosclerosis, high blood pressure, diabetes.** It is the surest antidote of **uric acid,** the great poison of the present generation.

Six sample quart bottles of **VITTEL GRANDE SOURCE** will be sent **Free** on request of any doctor. : :

the French Minéral table water
GRANDE SOURCE

Diphtheritic Otitis Media.—William J. Mellinger (*California State Journal of Medicine,* April, 1923) writes that he has seen eleven cases in three years, of infection of the middle ear with Klebs-Loeffler bacilli; only one of these was a primary infection with virulent diphtheria bacilli. The writer thinks that infection of the middle ear with nonvirulent diphtheria bacilli is of rather frequent occurrence and would be recognized if all cases of middle ear infection were cultured routinely. Instillations of argyrol into the nose and filling of the external auditory canal with sixty per cent. alcohol for twenty minutes was a successful routine treatment.

Diet During Pregnancy.—Eugene Cary (*Illinois Medical Journal,* March, 1923) divides gestation into three periods, from a dietary viewpoint. The first period corresponds to the first three months and during this time it is essential to crowd carbohydrates and supply small quantities of nourishment at frequent intervals. The second period is from the third to the eighth month, and here it is necessary to overcome intestinal stasis and supply adequate calcium in the diet. The third period is composed of the eighth and ninth months. In this last period we must overcome a tendency of the fetus to overgrow, and we must adjust the diet of the mother in such a manner that there cannot be an accumulation of uric acid and nitrogenous waste products in the body.

Heliotherapy in Infectious Diseases of Bones and Joints.—Emil S. Geist (*Minnesota Medicine,* April, 1923) believes that there are many other chronic infections of bones and joints besides tuberculosis which are benefitted by the rays of the sun properly used. These conditions are osteomyelitis, chronic arthritis, gonorrheal arthritis, rickets, influenzal swollen joints and circulatory disturbance of the feet. There are few dangers in the application of heliotherapy, and it can be used at home as well as in an institution. The point of the treatment is to achieve a tan but not a burn. Geist believes that the time has come for hospitals to use their roofs and porches and surrounding grounds for the application of heliotherapy.

Pharmacodynamic and Therapeutic Properties of Geneserine.—H. Surmont and M. Polonovski (*Bulletin de l'Académie de médecine,* February 27, 1923) note that in 1915 Polonovski and Nitzberg isolated from Calabar bean a new alkaloid, geneserine. This substance is only feebly basic and yields no crystalline salts with mineral acids, but on mixing solutions of it and of salicylic acid in ether there is obtained on evaporation a crystalline salicylate of geneserine. The latter is present in Calabar bean in equal or even greater amount than eserine. Its toxicity was found to be considerably lower than that of eserine, though in many respects its physiological effects are similar. It markedly stimulates smooth muscle tissue, including that of the intestine, and increases the salivary, pancreatic, and probably the intestinal secretions. It slows the heart by stimulating the cardioinhibitory centre, this effect no longer taking place when the vagi are cut. Whereas eserine slows the heart only after the appearance of toxic effects, such as vertigo and syncope, geneserine, in hypodermic doses of one to five milligrams, slows it without any toxic effects. In five cases of nervous dyspepsia of the hypopeptic type, coupled with Moutier's solar syndrome, rapid disappearance of painful epigastric palpitations and vasomotor disturbances of the face, with restoration of normal sleep, was obtained by daily ingestion of three quarters to one and a half milligrams of geneserine salicylate, divided into three doses before meals.

Levator Hernia.—H. C. Chase (*Surgery, Gynecology, and Obstetrics,* December, 1922) states that while it is obvious that no conclusions can be drawn from one case, nevertheless from a study of the thirteen cases reported, the anatomy as shown in his case and in cadaver dissections studied, he feels justified in making the following deductions: 1. Pudendal hernia, although extremely rare, should be easily recognized (three points). 2. All cases should be divided into anterior, posterior, or combined types as the basis of operation. 3. Every case should be submitted to operation. 4. A knowledge of the anatomy, the type presented and application of the principles of the operative treatment of all herniæ should result in a cure in a large majority of cases.

Weight Reduction: Further Consideration of Its Effect on High Blood Pressure.—Robert H. Rose (*American Medicine,* January, 1923), from further experience with weight reduction and its effect on high blood pressure, concludes as follows: High blood pressure frequently drops quickly during weight reduction, and remains lower as long as a normal diet is followed. Many symptoms are relieved at the same time, such as palpitation, dyspnea, angina pectoris, and certain forms of headache. When the heart is embarrassed and the pulse irregular with high pressure, this treatment may relieve the whole group of symptoms. The results may be explained by the lessening of a toxemia due to carbohydrate fermentation and the creation of a beneficial intestinal flora.

Diagnosis of Cancer by Means of Serum Reactions.—J. A. Shaw-Mackenzie (*Lancet,* October 7, 1922) draws attention to a new test of cancer by means of a turbidity reaction in the serum. This test consists in adding an ether extract of cancer tissue, with or without saponification, to cancer serum. This is followed by an appearance of turbidity after incubation, which does not appear at all, or not to the same extent, with noncancerous serum. It is essential that the serum used should be as clear as possible, as otherwise it becomes necessary to differentiate between relative turbidities, this being especially marked in diabetic cases.

Attempts at Detoxication. — From experimental evidence, Karl Mayer (*Schweizerische medizinische Wochenschrift,* August 24, 1922) draws the conclusion that the nature of the action of cocaine is not a chemical one, but rests upon physicochemical colloidal processes. The toxic effect of cocaine may be diminished in experimental animals by the administration of calcium salts; cocaine is a pseudoantagonist of calcium and its effectiveness may be inhibited by calcium and increased by potassium, and therefore the manner of the action of cocaine is dependent upon the ionic balance between calcium and potassium. This antagonism between cocaine and calcium is dependent upon a change in the condition of the lipoids, especially of lecithin.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Thousands of busy practitioners turn to Gray's Glycerine Tonic Comp. whenever a restorative or reconstructive is needed, because their experience has shown them that it can be relied on to produce the results they seek.

Dysmenorrhea

is one of the most common and intractable affections that tax the skill of the practitioner. Fortunately, in

Hyperol

the practicing physician has a remedy that, owing its beneficial action to its regulation of the utero-ovarian circulation, promptly reduces the local congestion and thus effects an early relief from pain. Not the least, therefore, of the notable advantages of Hyperol, is the way it obviates, in the great majority of cases, any necessity for opiates or narcotic drugs, with their all too evident dangers.

But it is through its restoration of normal functions of the uterus and ovaries that Hyperol accomplishes its greatest benefits, for it thus enables medical men to produce results in **amenorrhea, dysmenorrhea, subinvolution and kindred** ills that are possible with few other remedies.

Valentine's Meat-Juice

In **Typhoid, Gastric** and **Other Fevers,** where it is **Essential** to **Sustain** the **Patient** without **Irritating** the **Weakened Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening** when **Other Food Fails.**

J. R. Wood, M. D., *Physician Sheltering Arms Hospital, Paint Creek, W. Va., U. S. A.:* "I have been using VALENTINE'S MEAT-JUICE in the treatment of Typhoid Fever cases in the Sheltering Arms Hospital, for the last two or three weeks, with the most gratifying results both to the patient and physician. I consider it the best preparation of animal food I have ever seen, in fact, the only one I have ever had any success with."

Dr. Genevaix, *Assistant Surgeon-Major, First Class, Hotel Dieu, Creusot, France:* "The patients to whom I have given the excellent preparation, VALENTINE'S MEAT-JUICE, have found their general condition rapidly improved by it, and in the convalescence from continued Fever (Typhoid and Para-Typhoid) it gives the best results."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

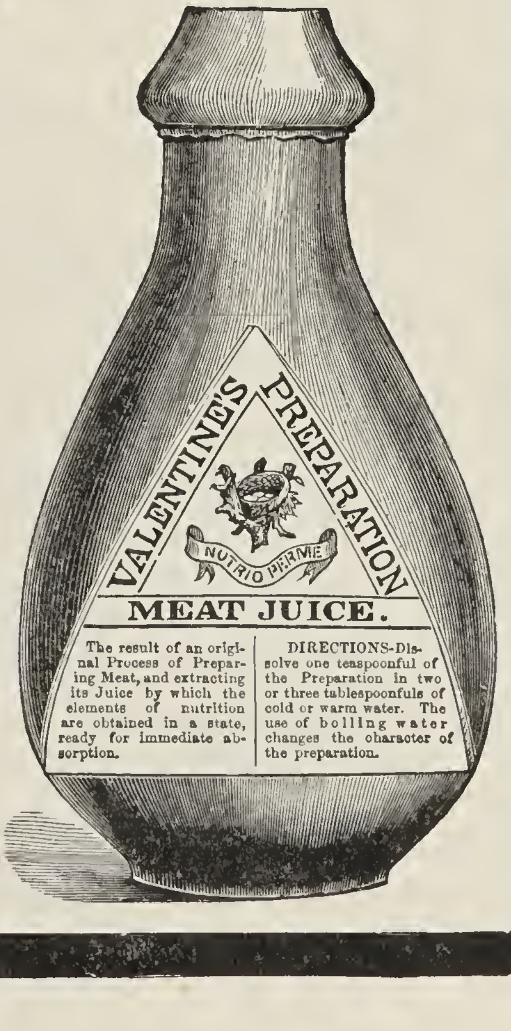
Richmond, Virginia, U. S. A.

S 193



The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Treatment of Cholelithiasis.—Farquhar Macrae (*British Medical Journal,* November 25, 1922) says that the radical treatment of gallstones is purely surgical. It is very doubtful whether much can be done by medical treatment to diminish the liability to attacks of colic, or to palliate the accompanying dyspepsia. Any attempt to render the bile antiseptic by such drugs as urotropine in doses which would not do harm otherwise seems obviously futile, and it is very doubtful if the bile can be so altered in consistency by drugs as to affect its amount or its rate of expulsion. But the great majority of victims of cholelithiasis suffer throughout only from indigestion, and if they are willing to submit to the discomfort and inconvenience of this it is doubtful whether the surgeon is justified in urging operation upon them.

Treatment of Diabetic Gangrene.—Howard F. Root (*Boston Medical and Surgical Journal,* December 14, 1922) reports seven cases in which operation was successfully performed. The prevention of gangrene of the feet in diabetes depends on conservation of the circulation by exercises, massage and rest, avoidance of cutting corns, pricking blisters, cutting toenails too closely, and careful aseptic treatment of minor lesions. The first step in the treatment of infections is to secure circulatory support by elevation of the foot. If gangrene and infection are established amputation is indicated as soon as nonoperative treatment ceases to give improvement. Operation is practicable in the presence of sugar, acidosis, or both. Fat or aged patients should not have fasting treatment in preparation. During forty-eight hours before and after operation the diet should consist of a moderate, or for a diabetic a liberal supply of carbohydrate food in the form of orange juice, oatmeal gruel with skimmed milk, shredded wheat, soda biscuits and egg albumen. Spinal anesthesia is the first choice, gas and oxygen the second, ether only as a last resort and for the briefest space of time.

Chemical Changes in the Blood of the Dog After Intestinal Obstruction.—Russell L. Haden and Thomas G. Orr (*Journal of Experimental Medicine,* March, 1923) studied the blood chemistry of normal dogs and of dogs in which various types of intestinal obstruction were produced. After ligation of the duodenum, ligation of the duodenum and gastroenterostomy, and ligation of the ileum, there was a gradual fall in the chlorides and a rise in the CO_2 combining power, with an increase in the nonprotein nitrogen. The changes in the chloride metabolism are the most striking feature of the intoxication due to high obstruction. The authors suggest that the fall in chlorides is probably due to a utilization of the chlorine ion in the course of the intoxication, and that this use of chlorine may be a protective measure on the part of the body. The sugar, uric acid, and creatinin show nothing unusual. The urea nitrogen was found to be a good index of the protein destruction. It is pointed out that on the basis of the similarity of the blood findings in intestinal obstruction, acute lobar pneumonia, and serum disease, these widely varying conditions may have a common chemical basis.

Sodium Citrate in Congestive Disorders.—J. Lépine (*Presse médicale,* June 24, 1922) calls attention to the value of sodium citrate in congestive states or chronic disturbances of the circulation unassociated with marked vascular lesions, notably in uricemic cases and in the congestive disturbances of the menopause. Doses of two to six grams a day may in many patients be continued for a long period without untoward effects, and the remedy proves very useful in reëstablishing circulation.

Supplementary Protein Value of Peanut Flour.—Walter H. Eddy and Rena S. Eckman (*Journal of Biological Chemistry,* February, 1923) describe experiments in which the protein supplementary power of peanut flour is compared with that of muscle protein by feeding rations which contained only about ten per cent. of protein, six or seven per cent. of this being contributed by wheat flour, and the rest by peanut flour or meat residue, respectively. These rations were further supplemented by three per cent. of butter fat, four per cent. salts, and brought to nearly equal calorie value to the gram. The animals fed on the peanut flour showed slightly better growth than those fed on meat, and were markedly superior in reproduction. The actual protein intakes on the two diets did not vary widely, the calculated difference being 0.08 gm. daily. The peanut series intake averaged slightly more per day than the meat series.

Pernicious Anemia: An Analysis of 117 Cases.—P. N. Panton, A. G. Maitland-Jones and George Riddoch (*Lancet,* February 10, 1923) studied the clinical records of 117 patients, of whom the average age was forty-six years, ranging from twenty to sixty-eight, and the average duration of symptoms up to admission to the hospital was seventeen months, ranging from seven days to six years. Weakness occurred in 107 patients, in forty-nine of whom it was the chief complaint. Thirty-three patients noticed a change in color. The chief complaint of eight patients was loss of weight and twenty-six seemed to be emaciated. Fever, with an average range of temperature between 99° and 100° F., occurred at some time in ninety cases. Generally, disappearance of the fever occurred simultaneously with improvement in the general condition and also the more acute the condition the more constant was the presence of fever. Eighty-six patients complained of gastrointestinal symptoms; in fifty-three cases such complaints were primary. Fifty-one patients complained of vomiting, thirty of diarrhea, twenty-six of anorexia and twenty-four of epigastric pain.

Oral sepsis has no definite etiological significance in pernicious anemia, although it may produce a secondary anemia. While achylia is a frequent occurrence, it is not an essential etiological factor. Hematemesis occurred in three patients, but was copious in only one. The spleen was palpable in twenty-one cases and the liver was enlarged in nineteen cases. Sixty-three patients complained of cardiovascular symptoms and sixty-two had cardiac murmurs. Twenty-five patients complained of headache and eighteen of numbness and tingling of the hands and feet. The urine showed albumin in twenty-four patients, bile in two and sugar in one. The author warns against accepting the reports of cures in pernicious anemia without confirmation.

Many Babies Die of Summer Complaint—

Breast Milk Might Have Saved These Lives

Every physician knows the importance of breast-feeding as a safeguard in the prevention of gastro-intestinal disturbances.

This information should be convincingly brought to the attention of every mother.

The physician also knows that where breast milk is not available—a properly modified, clean, nutritious substitute should be selected.

For the average normal baby, Eagle Brand milk (which is made from pure, fresh, full-cream cows' milk) is a clean, nutritious food.

This product, because it is clean and easily digested, has been used with good results in gastro-intestinal disturbances. No milk-borne epidemics have ever been traceable to Eagle Brand milk.

Schieffelin & Co.
NEW YORK

Indications for Opium in Cardiac Therapy.—Daniel Routier (*Journal de Médécine de Paris,* March 17, 1923) advises opium in anginiform crises, in acute edema of the lungs, and in dyspnea of cardiac insufficiency. Morphine may be used in the sleeplessness of complete cardiac decompensation, and instead of diminishing the urinary output in dropsical cases it usually increases it. In attacks of paroxysmal tachycardia it is also indicated, especially in those which last for days at a time and which tend to produce cardiac insufficiency from distention. Finally, morphine is a drug which the cardiologist has frequent occasion to use, and, while its action is indirect, it adds greatly to the comfort of the cardiac patient and really merits a place among the cardiac tonics.

Extrapleural Thoracoplasty in the Treatment of Pulmonary Tuberculosis.—P. Bull (*British Medical Journal,* December 23, 1922) states: 1. That good results can be achieved by means of extrapleural thoracoplasty in cases of unilateral or mainly unilateral pulmonary tuberculosis which is not cured by rational expectant treatment or pneumothorax. 2. That an operation should be performed only after an exhaustive conference with the attending physician on the case, who must have been enabled by observation during a considerable period, to form a well considered opinion of the prognosis with continued expectant treatment. 3. That resection of the ribs should be carried out, under local or general anesthesia, through a paravertebral incision, so that the posterior part of the ribs from the eleventh, or in any case, from the tenth to the first inclusive, can be removed. 4. That if a cavity remains, it can be brought to collapse by means of intrathoracic transplantation of fat. 5. That medical practitioners should acquire knowledge of the indication and results of this operation, as one third of the patients, who would otherwise be doomed, can be saved thereby.

Emetine Bismuthous Iodide in the Treatment of Amebiasis.—P. Manson Rennie (*Lancet,* December 30, 1922) finds that the therapeutic action of emetine bismuthous iodide may be considered to have a definite curative effect on amebiasis, although sometimes it may be necessary to carry out two or three courses to effect a cure. Emetine injections, although palliative, cannot be considered a cure in this sense. The following rules should be observed in regard to its administration: 1. The treatment must be regulated by the tolerance of the patient; the drug need not be pushed to tolerance in every case. 2. The patient must be treated in bed; the diet should be light and easily assimilated and may be varied with toast and eggs and not necessarily confined to milk. 3. Delayed vomiting (four hours, after taking the drug) does not indicate that the drug will not be absorbed, but rather that it is beginning to take effect. 4. Diarrhea is of favorable import and is typical of this drug; there are usually three or four diarrheic movements a day, resembling the dregs of meat extract. 5. The restriction in diet for a month or so after treatment is important and the patient should receive advice on this point before discharge. 6. The increase in weight is very striking after a successful course of treatment with emetine bismuthous iodide.

Varicella and Ultraviolet Rays.—Arnold Sack (*Münchener medizinische Wochenschrift,* No. 16, 1922) suggests that it is very probable that a preliminary irradiation with ultraviolet rays markedly sensitizes the skin and that it activates and mobilizes the process of the eruption in varicella to a marked degree.

Sheep Asthma and Its Cure by Repeated Skin Reactions.—Trabaud and Charpentier (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* March 29, 1923) report the case of a soldier who suffered from nightly attacks of precordial discomfort and constriction, paroxysmal cough and wheezing which continued until dawn. Inquiry revealed that he had had occasional attacks of this sort ever since the age of six years. An attack could be brought on at will by holding his nose for a few minutes in a bit of wool freshly shorn from a laboratory animal. The symptoms began in three minutes and in seven minutes the leucocyte count dropped from 7,200 to 3,400. The treatment consisted in applying for a few hours, at first daily, then on alternate days, two samples of sterilized wool, one from a sheep and the other from a mattress, on scarified areas of one centimetre size over the opposite deltoids. The reactions on the two sides were alike throughout. On the first day, there developed at once a patch of giant urticaria, which disappeared rapidly when the dyspnea set in at night. On succeeding days the reaction became progressively less and the attacks of dyspnea simultaneously became milder. In two months the patient was cured, and could sleep on a wool mattress without symptoms. Attention is called to the prolonged maintenance of noxious properties in the proteins of the mattress and the fact that these properties were not annulled by sterilization.

New Method of Testing Liver Function With Phenoltetrachlorphthalein.—Sanford M. Rosenthal (*Bulletin of the Johns Hopkins Hospital,* December, 1922) says that the results reported by his method are quantitative and within certain limitations are independent of the condition of the bile channels. He believes that the rate at which the liver removes the dye used from the blood stream gives an index of the functional capacity of the entire organ. Phenoltetrachlorphthalein was injected intravenously into normal dogs, into those in which chloroform poisoning and phosphorus poisoning had been produced, and into animals in which the common and cystic bile ducts had been ligated. The following experimental results are noted: The concentrations reached in the plasma of normal dogs, after five mg. to the kilo injections, were strikingly constant. Approximately ten per cent. is present in two minutes, eight per cent. in three minutes, and from a large trace to absence in fifteen minutes. The rate of disappearance was higher in two cats, and more rapid in one rabbit. Variation of the dose has a direct influence on the curve obtained. After injury to the liver parenchyma there was a marked increase in these concentrations, with a greatly prolonged rate of disappearance. If repair has taken place the curves approach normal. In jaundice due to mechanical obstruction the curves differ widely from those obtained in jaundice associated with extensive degeneration of the hepatic cells.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

MISCELLANY.

Wassermann Reaction in the Johns Hopkins Hospital.—Albert Keidel and Joseph Earle Moore (*Bulletin of the Johns Hopkins Hospital*, January, 1923) present the results of a statistical survey of the sera of about forty-five thousand patients on whom Wassermann tests have been done since January, 1918. The material is of sufficient magnitude to make possible the drawing of accurate conclusions. The chief point brought out by this study, the results of which are too detailed to describe here, is the necessity of making a Wassermann test a routine procedure on every patient who enters a hospital.

Quantitative Flocculation Test for Syphilis.—Henry M. Feinblatt (*Journal of Laboratory and Clinical Medicine*, December, 1922) in a comparison of five hundred cases with the Wassermann, using a simplified Sachs-Georgi technic, obtained the same result in 93.8 per cent. of the cases in which parallel Sachs-Georgi and Wassermann tests were carried out. In the thirty-one conflicting cases, sixteen were positive to the Sachs-Georgi and fifteen to the Wassermann. In the sixteen patients who gave a positive Sachs-Georgi and a negative Wassermann, fifteen showed definite clinical evidence of syphilis. Eleven of the fifteen patients with a positive Wassermann but negative Sachs-Georgi showed definite clinical evidence of syphiliis.

Benign Albuminuria of School Children.—On examining five thousand school children Paul Lauener (*Schweizerische medizinische Wochenschrift*, December 21, 1922) found that 6.7 per cent. of those between the ages of six and seven years showed albuminuria, as did also twenty-seven per cent. of those between the ages of ten and eleven years, and thirty-eight per cent. of those between fifteen and sixteen years of age. The group of children that came from more prosperous homes and showed more marked growth showed more cases of albuminuria. The kidney is involved only as an excretory organ and the growth is subjected to its own conditions of metabolism, which lead to albuminuria. Treatment for this condition is unnecessary and may even be harmful, as it results in psychoneurotic conditions.

Recent Investigations on the Coagulation of Blood.—A. Fonio (*Sshweizerische medizinische Wochenschrift*, January 11 and 18, 1923) conducted some investigations on the various factors of coagulation, on the valence and time of coagulation, and on the tensile strength and retractility of the thrombus in different diseases and according to his own technic; he determined their relation to one another and also the dependence upon the number of platelets, etc. The diseases in which these were studied are exophthalmic goitre, myxedema, cretinism, tuberculosis, pregnancy, leucemia and hemophilia. Plasma rendered incoagulable and deprived of all the formed elements coagulates on the addition of thrombin, but the retraction of the fibrin occurs only if blood platelets have been added originally. Erythrocytes and leucocytes behave indifferently toward coagulation. The retractility is of special significance as it produces physiological ligation of the bloodvessels; if it does not occur, severe hemorrhages and secondary hemorrhages occur very readily with operations. In hemophilia the thrombin is insufficient or inadequate in amount, the fibrinogen being sufficient.

The combined blood examination enabled the author to know before the operation whether the hemorrhage would be severe, normal, or abnormally slight (myxedema) and whether secondary hemorrhages were to be feared; he was also enabled to improve the coagulability of the blood by preliminary treatment (with coagulen). In this way hemophilia, purpura, etc., may be differentiated diagnostically, and it is also possible to ascertain whether the deficiency of fibrinogen and thrombin, or whether the physical and physiological properties of the white thrombus and the formation of the fibrin is the cause of the hemorrhages in leucemia, secondary anemia, etc. The treatment will naturally be directed accordingly.

Sudden Death from Anaphylactic Shock.—F. W. Sumner (*British Medical Journal*, March 17, 1923) reports a case of sudden death within five minutes after a prophylactic dose of one thousand units of diphtheria antitoxin. There was no previous injection of any sort. This was probably a case of status lymphaticus with enlargement of the tonsils and adenoids and a persistent thymus. The patient showed an intolerance to the vicinity of horses. The horse serum is no doubt the offending factor in these cases. To avoid such accidents the author recommends a preliminary intravenous injection of 0.5 c. c. of the ten per cent. diluted serum and, if no adverse symptoms arise in an hour, the subcutaneous injection of the remainder of the dose should eliminate the possibility of anaphylactic disaster; a preliminary intravenous injection of a preparation consisting of sodium carbonate five grains, gum arabic one dram, glucose one dram, in normal saline solution up to thirty c. c., together with an intramuscular injection of a sterile solution of one grain of calcium chloride dissolved in ten minims of normal saline solution an hour before the serum injection, should also do away with any chance of anaphylaxis.

Therapeutic Increase of the Coagulating Power of the Blood, Especially in Surgery.—As a result of his own observations and an extensive study of the literature, P. F. Nigst (*Schweizerische medizinische Wochenschrift*, December 21 and 28, 1922) comes to the conclusion that hemorrhage and the coagulation of blood show a distant relationship, as is generally assumed. It has been shown that a few drugs lead to an increased power of coagulation of the blood in vitro, but this does not prove that they are hemostyptics in the body. Clinically and therapeutically, these are variously estimated in the literature and opinions are even contradictory. The author agrees with those who deny their value. Stimulating röntgen irradiations of the spleen as well as of other organs and also in splenectomized patients, increase the coagulating power of the blood in vitro, but this fact has no significance in practical hemostasis in surgery. In this respect, the local application of the remedies having an accelerating effect on coagulation of the blood (according to the author's experience best as a tampon in the form of a piece of muscle, peritoneum, or fat) is recommended. These local applications of hemostatics may be useful, but only the classical surgical methods are reliable.

Bowel Torpor in the Elderly

is usually the result of a progressive atony of the bowel, with a gradual decrease of the natural mucus and other secretions. The loss of moisture dries the feces and interferes with their free and easy passage. Under such conditions

INTEROL

serves as a safe and efficient substitute for the physiologic secretions. Following its systematic use, the bowel contents are kept soft, the intestinal canal—especially the large intestine—is adequately lubricated, and the feces are passed along and evacuated in due time without straining, pain, or discomfort.

INTEROL thus constitutes an ideal medium for the relief of bowel torpor in patients of advanced age.

DIRECTIONS:

In treating the elderly, begin with a tablespoonful morning and night on an empty stomach, increasing or decreasing as conditions require.

Sample and Interol brochure on request.

The Vitamine Content of Certain Proprietary Preparations.—The experiments recorded by Katharine H. Coward and A. J. Clark (*British Medical Journal,* January 6, 1923) show that in none of the proprietaries examined were the vitamines concentrated on the commercial scale. This result was only to be expected, for the concentration of the two more stable vitamines (A and B) is a most difficult process, even on a laboratory scale, and when successful the final yield of purified vitamine represents a minute fraction of the total quantity of vitamines present in the raw material. These experiments show that under normal conditions of life an adequate supply of vitamines can be easily ensured by including in the diet a suitable amount of "protective foods," such as milk, butter, green vegetables and fruit, and that no advantage is to be gained by trying to obtain these substances in drug form.

Vaccination Against Varicella. — Wilhelm Knoepfelmacher's studies (*Monatsschrift für Kinderheilkunde,* A. Czerny Festschrift, March 25, 1923) show that: 1. In varicella, it is possible to produce vesicle formation (varicellization) by the inoculation of the vesicular contents. 2. The contents of the inoculated vesicles can be reinoculated, and therefore contains the specific virus. 3. It is probable that a generalized exanthem may be produced in this way. 4. It is practically proved that varicella may be transmitted in this way. 5. The local inoculation leads to a protection by inoculation, which need not become evident before the nineteeenth day after the inoculation. 6. Reinoculation in successfully varicellized patients remains negative, as well as in children who have recovered from varicella. 7. Experiments on complement fixation for the demonstration of antibodies in varicellized are necessary; the experiments detailed by the author were without result.

Kidneys and Tonsillar Infection.—Edmund Cautley (*Archives of Pediatrics,* February, 1923) states that tonsillar infection is often the cause of hematuria and albuminuria, or even acute nephritis and that tonsillectomy is a necessary mode of treatment. These attacks are more common in children than in adults. They are usually mild and end in recovery in two to six weeks; occasionally they are severe and end in chronic albuminuria. The mildest type of case is characterized by bloody discoloration of the urine and albuminuria; there may be a few hyaline and granular casts. There is usually a slight or no fever and the child appears perfectly well. The kidneys can excrete dead or living bacteria without setting up nephritis; even if there is an actual nephritis it need not necessarily be either severe or generalized. A focal infection and local damage in one kidney can explain the mild cases. From the diagnostic viewpoint, a focus of infection, especially in the tonsils, should be sought. The treatment includes a diet of milk and carbohydrates, fruit and vegetables; citrate of potash during the stage of hematuria and a mild preparation of iron. Vaccine treatment does not seem necessary. The author recommends a watchful waiting policy with the enucleation of the tonsils until the local infection has subsided and the blood has disappeared from the urine, except in severe cases (uremic symptoms), when it might be advisable to operate earlier.

Blood Sugar Content of Capillary Blood as Compared With That of Venous Blood.—Isaac Neuwirth and Israel S. Kleiner (*Journal of Laboratory and Clinical Medicine,* May, 1922) found in twenty individuals that the capillary blood sugar closely parallels the venous blood sugar, and for all clinical purposes may be accepted as equivalent.

Backache.—William Dameshek (*Boston Medical and Surgical Journal,* December 7, 1922) divides treatment into general and local. General treatment consists of measures against constipation, visceroptosis, underlying complexes, wrong methods of standing or walking, etc. Local measures are, 1, for mild cases, a belt or adhesive strapping; 2, for more severe cases, a course of rest and then a tight corset; 3, for severe cases, the breaking of adhesions by manipulation—the osteopathic method.

A Cytological Study of the Nature of Rickettsia in Rocky Mountain Spotted Fever.—F. M. Nicholson (*Journal of Experimental Medicine,* February, 1923) presents evidence to show that Rickettsia are entirely distinct from all known cellular components. Diplobacillary forms were most abundant in the early stages of the reaction, and single bacillary bodies towards the termination. Other slight differences in morphology from Wolbach's account were noted in the organisms in the tissues of both ticks and guineapigs.

Special Training in Home Nursing.—Alfred Worcester (*Boston Medical and Surgical Journal,* October 5, 1922) maintains that the greatest need of nursing service is now, always has been, and always will be, in the home of the patient; that special training for home nursing is necessary; that this can be given only in the home, and that it can best be given during the nurse's pupilage. It is unfair, both to the public and to the pupil nurses, for a training school not to include this special training in its curriculum.

Studies on Lymphoid Activity.—Waro Nakahara (*Journal of Experimental Medicine,* April, 1922) has demonstrated by this study that resistance to transplanted cancer may be induced in mice by the intraperitoneal injection of olive oil. The maximum degree of resistance appears to be about the tenth day. Histologically, before the establishment of resistance, there is a proliferation of the cells of the lymphoid germ centres, and after the cancer inoculation, there is lymphoid infiltration about the grafts, a second stimulation of the lymphoid germ centres and an increase in circulating lymphocytes.

Pathogenesis of Köhler's Disease.—P. Caffier (*Monatsschrift für Kinderheilkunde,* March, 1923) concludes that both internal and external causes are concerned in the development of the sharply circumscribed symptom complex of Köhler's disease. The most probable course is an inhibition in development and trauma. A severe injury of the foot is probably associated with injury of the bloodvessels, resulting, possibly, in a diminution in the blood circulation of the navicular bone, while every growing bone requires an increased blood supply. It is possible that as a result of this hypothetical disturbance in nutrition only a diminution of the transformation of the cartilage into bone results, but not an inhibition of the proliferation of the cartilage.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Thousands of busy practitioners turn to Gray's Glycerine Tonic Comp. whenever a restorative or reconstructive is needed, because their experience has shown them that it can be relied on to produce the results they seek.

Dysmenorrhea

is one of the most common and intractable affections that tax the skill of the practitioner. Fortunately, in

Hyperol

the practicing physician has a remedy that, owing its beneficial action to its regulation of the utero-ovarian circulation, promptly reduces the local congestion and thus effects an early relief from pain. Not the least, therefore, of the notable advantages of Hyperol, is the way it obviates, in the great majority of cases, any necessity for opiates or narcotic drugs, with their all too evident dangers.

But it is through its restoration of normal functions of the uterus and ovaries that Hyperol accomplishes its greatest benefits, for it thus enables medical men to produce results in **amenorrhea, dysmenorrhea, subinvolution and kindred** ills that are possible with few other remedies.

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.

The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY.

Early Diagnosis of Acute Appendicitis.—R. Rove (*Presse médicale*, May 5, 1923) lays stress on an epigastric syndrome met with at the outset in severe cases of appendicitis. It occurs, on an average, in the first six hours of the attack, preceding the well known manifestations in the right iliac region. The patient complains of severe pain in the epigastrium and vomits frequently. In bed he lies on his back, but the thighs are not flexed on the abdomen. Examination reveals marked tenderness confined to the left upper epigastric region, together with cutaneous hyperesthesia in the same area. The upper portion of the left rectus is contracted and rigid. On the other hand, in the right iliac region there exists, in the majority of cases, no rigidity, tenderness or hyperesthesia. Celiotomy in this early stage reveals that the great omentum is traveling toward the appendix, from which it is separated by a distance corresponding to the time elapsed since the appearance of the epigastric symptoms. In the latter part of the disturbance the omentum is closely applied to the appendix, which shows a gangrenous area and soon after perforation. Operation before the syndrome has ceased, i. e., before the appearance of signs in the right iliac region, is a sure preventive of peritonitis and saves the patient from almost certain death. This syndrome is rarely observed in hospitals, too much time having elapsed from the onset and the time of admission. It is perhaps to be ascribed to irritation of the nerves of the great omentum, due either to its rapid displacement toward the appendix or to the extreme toxicity of the products absorbed by it. The omentum being derived from the dorsal part of the primitive mesogastrium, i. e., from the vicinity of the greater curvature of the stomach, the irritation doubtless becomes manifest in sensory and motor evidences in the epigastric region, as though the greater curvature were diseased. Enriquez, Guttman, and Rouvière, moreover, have shown that pressure by the inflamed appendix induces a hypotensor reflex which seems to travel by way of the solar plexus and appears as a reflex of acute excitation of the pneumogastric.

Iodine in the Treatment of Refractory Malaria.—Cheinisse (*Presse médicale*, May 5, 1923) refers to the experiences of Roubachkine in treating twenty cases of refractory chronic malaria with iodine, administered either in the form of a ten per cent. iodine tincture, of which five to ten drops were given twice daily, or of a solution of two grams of iodine and five grams of potassium iodide in one hundred grams of water, of which twenty to thirty drops were taken twice daily. Continued for about a month, this treatment brought about cessation of the recurrences in all but two cases. In spite of this, blood examinations showed persistence of the process of schizogony in the parasites, although no febrile paroxysms occurred. The spleen in some instances was reduced rapidly and markedly; in others, remained unchanged. Iodine seemed to reactivate quinine. In two cases due to plasmodium præcox, in which gametes remained in the blood in spite of the prolonged use of quinine, six or seven days of iodine treatment, followed by three injections of 0.5 gram of quinine caused the gametes to disappear. Good results were obtained in refractory chronic cases by the combined use of iodine and quinine in the form of a mixture in equal parts of five per cent. tincture of iodine and ten per cent. alcoholic solution of quinine hydrochloride, of which twenty-five drops were taken by mouth twice a day for three successive days in each week, the treatment being continued for at least two months. In other instances injections of a mixed solution made by means of the addition of antipyrine were given deeply in the subcutaneous cellular tissues, with gratifying results. Acute paroxysms in chronic cases resistant to quinine were rapidly cut short by such injections, which also proved valuable in severe chronic cases with complications such as edema and ascites.

Practical Points on Purgation.—Lewis W. Elias (*Southern Medical Journal*, August, 1923) protests against the theory that the first thing in case of illness is a thorough, and often continuous, clearing of the alimentary canal. His point is not that laxatives should never be given, but that they should be given only for a definite indication, and then with proper safeguards. Two such indications are: The presence of symptoms definitely suggesting the injurious intestinal absorption that enemas have failed to relieve, and an edematous patient who may need depletion. Merely because a patient is sick is no reason for a purge. Most patients are best helped by water, food, and such hygienic measures as tend to build up their resistance. If the lower bowel needs emptying, do it with an enema. A purge draws a large amount of water from the body tissues, so when a purge is given the patient should also be given plenty of water. The same care and thought should govern the use of a cathartic as the use of any other drug.

Renal and Hepatic Forms of Glycosuria.—M. Labbé (*Paris médical*, May 5, 1923) adduces cases illustrating the fact that, in the diagnosis of diabetes mellitus, there must be taken into account instances of disturbance of glucose metabolism dependent upon the nervous system, the ductless glands, the kidneys, and especially the liver, which differ materially in their clinical course from diabetes. In the latter, the disturbance of glycoregulation is more intense; it is permanent and, in the severe cases, even progressive; in the severe cases, too, it is associated with disturbances of protein and fat metabolism. In nondiabetic glycosurias, the disturbance of glycoregulation is transitory and generally curable. It exhibits no tendency to progress, and any associated disturbance of protein and fat metabolism is much less intense than in severe diabetes. The treatment is likewise very different. Reduction of carbohydrates is not indicated; indeed, in glycosuria of hepatic origin, recovery is best secured by suppression of meat, reduction of fats, and a diet of milk and starches. Thus in all cases of glycosuria, especially in young subjects, an exact diagnosis is needful. It should be based not only on the clinical data, but also particularly on blood sugar determination and tests for hyperglycerin upon ingestion of glucose. The latter test is indispensable in the more uncertain cases to exclude diabetes mellitus. In hepatic glycosuria the treatment consists, aside from the diet, in stimulating the liver by the administration of hepatic extracts, cholagogues, calomel, and alkaline cures, of which the type is the Vichy cure.

Many Babies Die of Summer Complaint—

Breast Milk Might Have Saved These Lives

Every physician knows the importance of breast-feeding as a safeguard in the prevention of gastro-intestinal disturbances.

This information should be convincingly brought to the attention of every mother.

The physician also knows that where breast milk is not available—a properly modified, clean, nutritious substitute should be selected.

For the average normal baby, Eagle Brand milk (which is made from pure, fresh, full-cream cows' milk) is a clean, nutritious food.

This product, because it is clean and easily digested, has been used with good results in gastro-intestinal disturbances. No milk-borne epidemics have ever been traceable to Eagle Brand milk.

Icterus Neonatorum.—For the purpose of clearing up the still unknown etiology of icterus neonatorum, G. Linzenmeier and Lillienthal (*Zentralblatt für Gynäkologie,* November 25, 1922) applied the Widal liver function test and found a parallelism between insufficiency of the liver and icterus, in so far as all those newborn infants in whom the test resulted positively and who showed a leucopenia, were later affected by icterus, whereas those with leucocytosis remained free from icterus. It is therefore possible that the icterus neonatorum is based upon an initial insufficiency of the liver in the newborn in the sense of the Yllpö theory.

Colloidal Benzoin Reaction in Disseminated Sclerosis.—Souques, Mouquin and Walter (*Presse médicale,* May 2, 1923) found the colloidal benzoin reaction feebly or definitely positive in eleven out of twelve cases of disseminated sclerosis. The type of response was not constant, sometimes simulating that of general paralysis or that of arrested syphilis, or again, not resembling any of the types ordinarily met with in neurosyphilis. While the colloidal benzoin reaction cannot be regarded as an absolutely specific test for syphilis of the central nervous system, it is only in disseminated sclerosis that a weakly or definitely positive colloidal benzoin test of any type may be found in an otherwise normal cerebrospinal fluid.

Tolysin.—H. G. Barbour, E. Lozinsky, and C. Clements (*American Journal of the Medical Sciences,* May, 1923) give the clinical histories of a number of cases in which they have tried tolysin. Twelve were cases of acute and subacute rheumatic fever, seven of other forms of arthritis. In addition some observations are made upon the action of the drug as an antipyretic and analgesic. Tolysin is the short name of the ethyl ester of paramethylphenylcinchonic acid, which has recently been recommended as an improvement upon the salicylates for the treatment of such diseases as those mentioned. They found it efficient in acute rheumatic fever. The usual dose required for complete relief of the symptoms was from ten to sixteen grams. Partial relief was obtained with seven to eight grams. A satisfactory routine they found to be to give two grams every two hours for three doses, then two grams every four hours. No gastric symptoms were elicited, and albuminuria was increased in only one case. Satisfactory results were obtained in six out of seven cases of arthritis of other types, including acute infections and chronic joint pains. In ordinary colds and headaches its effects appear to be equivalent to those of aspirin, but the action is slower and larger doses are needed. In acute tonsillitis one to two grams, which can be repeated, exert a good antipyretic action. So far as safety is concerned they state that two different patients received each fifty grams of the drug within eight days without any untoward symptoms, and that their recent laboratory investigation seems to show that the body is unable to absorb much more than the therapeutic dose. Finally they maintain that the employment of tolysin may be substituted for any internal salicylate medication, that it is particularly efficient in acute rheumatic fever, and that, on the basis of evidence at present available, it can apparently be administered harmlessly in this and in other forms of arthritis.

Sweating From the Viewpoint of the Loss of Energy.—Max E. Bircher (*Schweizerische medizinische Wochenschrift,* December 30, 1922) was enabled to show that during the proces of sweating (induced by arc lights for ten to twenty minutes) the consumption of oxygen by the body rises on an average thirteen per cent. and this increase, which depends upon an activation of the tissue metabolism, runs parallel with an increase in the body temperature for several hours. The pulse and respiration frequency rise equably with the duration of the irradiation and heating of the body, but the blood pressure sinks (at the most about ten mm. Hg). On the whole, artificial sweating makes only slight demands on the organism and produces a considerable improvement in the condition of many individuals, with a slight diminution of the basal metabolism which is not harmful.

The Blood as a Guide to Early Diagnosis in Lead Poisoning.—Robert Craik (*British Medical Journal,* January 20, 1923) asserts that the presence of the blue line demands careful examination of the patient, but the diagnosis must always be independent of the blue line, which remains only valuable presumptive evidence. In lead poisoning the metal is always present in the urine and remains for weeks or months after treatment is undertaken. Punctate basophilia is more likely to be caused by lead than by anything else. It is pathological and should always be investigated; if it is caused by lead the urine will contain a trace of the metal even in the absence of other symptoms. The diagnosis of lead poisoning should depend, not on gross signs, but on suspicious symptoms and on the investigation of the blood and urine.

Indications for Surgical and Irradiation Treatment of Myomas.—Walter Fürst (*Schweizer medizinische Wochenschrift,* July 6, 1922) thinks that it is very difficult to decide whether irradiation is preferable to operation in some cases of myoma. He calls particular attention to those very large tumors where palpation is impossible and where it is desirable to exclude every suspicion of malignancy before resorting to irradiation. Palpation of the external contour of the tumor is not sufficient, but frequently the dilatation of the cervical canal, digital exploration of the uterine cavity, and the microscopic examination of the mucosa, or a protracted period of observation cannot be dispensed with. Only with such a procedure is there the possibility of subjecting only such cases of myoma to irradiation as can positively be relieved of symptoms by the x rays. The author maintains that those clinicians and physicians who assume the responsibility of the irradiation treatment, should at least keep the patients, in whom no curettage was done, under observation. He examines all women, who were treated once with irradiation, every three or four months, to determine any change in the matter of the hemorrhage or other symptoms and he endeavors to control the findings during the first few months after irradiation, in women suffering with carcinoma and myoma. With early irradiation at a single sitting, the patient is soon discharged, provided the proper indication for treatment was established. In this way the more or less protracted staying in bed is done away with.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Miscellany.

Painful Hypertrophy of the Breasts Cured by Oophorectomy.—Leriche (*Presse médicale,* May 5, 1923) reports the case of a woman of thirty-seven years whose breasts had been large and painful since the onset of menstruation at fourteen years. Menstruation was copious and prolonged. Of late the pain in the breasts had so increased as to prevent work and sleep. The organs were hard, with the lobules appearing as if injected with tallow, and a large tender node in the right axilla. An external discoid resection of both breasts by the submammary route was first performed, with little result. Three weeks later, injections of milk, previously found very effectual in Palet's cases, were given, without effect. Ten minutes' exposure to the mercury lamp at weekly intervals gave excellent results, but the effect was not maintained. Internal administration of mercury, iodide, and arsenic proved useless. After a year's fruitless treatment, menstruation becoming increasingly disturbing and palpation revealing diseased adnexa, celiotomy was carried out. Numerous adhesions were found between the sigmoid and two large tuboovarian cysts in which ovarian tissue was macroscopically absent. A subtotal hysterectomy was done. On the next day the breasts began to recede and the pain ceased. The breasts thereafter shrank further. The almost immediate reduction in size witnessed under milk injections or the mercury vapor lamp in some of these cases seems to show that the process is not a diffuse adenoma, but that abnormal vasomotor conditions constitute a major factor in it. The result obtained from oöphorectomy shows that the disorder, at least in some instances, originates in the reproductive organs.

A Statistical Study of Tuberculin Tests in Infancy and Early Childhood.—S. A. Wahl and H. J. Gerstenberger (*Archives of Pediatrics,* March, 1923) conclude that: 1. There is a slight increase of positive tests in the females over the males (sixty-one to fifty-four per cent.). 2. There is an increase in the percentage of positive reactions corresponding with the increase in age, being thirty-five per cent. in infants under six months of age, and eighty-seven per cent. in young children between three and four years of age. 3. Of different races and nationalities, the colored race gives the highest percentage of positive reactions. 4. Patients exposed to two or more sources of tuberculous infection showed a higher percentage of positive reactions than those exposed to only one. 5. When only one source of contact existed for a patient, the mother was found responsible for the highest percentage of positive reactions, a brother or sister for the next highest and the father for the lowest of the group. 6. Forty-four per cent. of the children giving positive tuberculin reactions gave a definite history of tuberculous contact, whereas, of those giving a negative history of exposure only fifteen per cent. reacted positively. 7. Scrofula gave the highest percentage of positive reactions and was followed by pulmonary tuberculosis, tuberculous adenitis, tuberculous osteomyelitis and pulmonary miliary tuberculosis. 8. By using the intracutaneous test, controlled by checking with a known case of tuberculosis, a higher percentage of positive reactions can be obtained, especially in cases of tuberculous meningitis and pulmonary miliary tuberculosis, than has been usually reported. 9. The intracutaneous tuberculin test, 0.1 c. c. of a one in one hundred solution, is in practically one hundred per cent. of the cases more sensitive in its reaction than the tuberculin tests performed either with the tattoo or the burr method; likewise, the test performed by the tattoo method is more sensitive than the burr, although the former is more difficult from a technical viewpoint. 10. The intracutaneous test with a one in a thousand solution has always been found positive even when stronger dilutions of one in ten and one in a hundred were used; the reactions with the stronger solutions have been in general more marked but the reaction with the one in a hundred dilution has been sufficient to convince the authors to choose it as their standard in performing the intracutaneous test.

Orthopedic Treatment of Rachitic Deformities.—Albert Wollenberg (*Deutsche medizinische Wochenschrift,* Nos. 17 and 18, 1922)) states that the following measures are necessary in the prevention and prophylaxis of rachitic deformities: The physical therapy should include passage, gymnastics (active and passive motions and motions against resistance), hyperemia (hot air baths, partial light baths and diathermy), radiotherapy (ultraviolet rays from the quartz lamp); regulation of the hygienic conditions, the diet and antirachitic medication (codliver oil) are valuable adjuncts. The adrenalin treatment has also been tired.

Arterial Pulse in Influenzal Pneumonia.—F. Leegaard (*Norsk Magazin for Laegevidenskaben,* August, 1922) contributes a study of the peripheral pulse of the carotis and radialis, drawing conclusions wherever possible as to the aortal curve. In the primary pulse wave of the author's cases of influenzal pneumonia, the curves are sharp and perpendicular as in acute febrile and infectious diseases, the sharp curve being more marked in the radialis curve than in the carotis pulse. This fact would suggest that the central pulse (the aortal pressure curve) would also show a slighter deviation of the primary wave, and lead to the conclusion that the sharp primary elevation of the arterial pulse must be of peripheral origin. In these cases the author feels he is confronted with a cardiectasis, extending to the arteries and capillaries, which is least noticeable in the large and medium arteries, and progressive toward the periphery. The tables show an increased incisure in both the carotid and radialis pulse, with a sharper curve in the former, probably due to peripheral conditions. The positive secondary elevation—the dicrotic—is also particularly marked in the radialis curve, and not so strongly developed in the carotid, which would suggest that the aortal pressure curve would likewise show but insignificant acceleration. The peripheral reflex must be considered as playing an important part.

The development of the incisure seems to depend on where the point of systolic end and diastolic beginning strikes the downward limb of the primary elevation. If this point is high up, a marked incisure is observed; as it descends the incisure diminishes, and becomes minimal in such cases where no point can be designated signifying the transition from systolic to diastolic, the pulse becoming monocrotic. In these cases the diastolic pressure is very low.

Constipation in Young Girls and Women—

especially those who spend much time indoors engaged in sedentary pursuits—is almost invariably attended by a retention of waste and toxic substances. Sooner or later these make their way from the bowel into the general system and give rise to a host of autotoxic ills.

Correction of this condition is imperative, and the safest, simplest and most effective remedy for the purpose is

INTEROL

a pure mineral oil of the proper density and viscosity to assure satisfactory lubrication of the intestinal canal, and thus relieve and correct bowel inactivity without the usual disagreeable effects of cathartics as commonly employed.

Besides lubricating the canal, INTEROL renders the feces soft and plastic, thereby promoting their easy passage and evacuation with gratifying freedom from discomfort and distress.

It would indeed be difficult to suggest any more serviceable and agreeable medium for the correction of constipation, with its attending autotoxemic conditions, than INTEROL.

Sample and Interol brochure on request.

Allied Drug and Chemical Corporation
2413 Third Ave., New York City

MANUFACTURERS OF ORASEPTINE—Internal and External Antiseptic, Wash, Spray and Douche.
ADACCO SALT—Effervescent Saline Laxative and Uric Acid Solvent.
VELOGEN—"The Doctor's Hand-maid and Household Emollient."

Directions:

To relieve the constipation of young girls and women, give two to four teaspoonfuls of INTEROL morning and night, increasing or decreasing the quantity as conditions require. As the bowels yield to the action of INTEROL, gradually cut down the dose to the least amount that—taken at bedtime—will assure a daily evacuation.

Palatability

In the administration of remedies, no factor, next to efficiency, is of greater importance than palatability. The psychological effect of a remedy is oftentimes as important as its physiological action.

ESKAY'S NEURO PHOSPHATES

furnishes not only a markedly effective form of the glycero-phosphates, but one that is particularly palatable. Patients do not tire of it on continued use, a paramount consideration in the treatment of neurasthenics.

SMITH, KLINE & FRENCH CO.

Sputum in Necrotizing Influenza Pneumonia.—Erich Liebmann (*Schweizerische Medizinische Wochenschrift,* July 20, 1922) states that the necrotizing pneumonia may be recognized only by the changes found in the sputum, which are the following: Macroscopically, the sudden transition from a hemorrhagic to a purulent character, the rapid increase in the amount and the diminution in consistency; microscopically, the appearance of elastic fibres, the predominance of degenerated neutrophile leucocytes and the appearance of large macrophages, loaded with abundant cellular particles. Attention is also called to the significance of the macrophages as cleansing factors in the alveolar parenchyma of the lung.

Bacteriology of Ozena.—Kozo Sakagami (*Lancet,* January 6, 1923) recapitulates his experiments as follows: 1. The socalled ozena bacillus, obtained from the nasal passages of ozena patients, agrees in all important points with the coccobacillus of Perez. 2. The latter is to be found only in ozena patients and not in persons suffering from other nasal diseases and healthy persons. 3. Symptoms closely resembling those of human ozena were reproduced experimentally in rabbits. 4. In the various immune tests with the author's coccobacillus the serum of ozena patients generally showed a weak reaction; with some patients, however (those tending toward recovery), the specific reactions were remarkably strong. 5. It could be demonstrated that the serum from a rabbit immunized against the author's coccobacillus produces various immune bodies with great intensity. 6. In animal experiments with this bacillus the presence of immune bodies in the serum was clearly demonstrable; on the other hand, the reactions of the serum of most patients were rather weak. This can be explained from the nature of the disease, which causes merely local changes, so that in the general circulation the antibodies appear only in small quantities. 7. From these experiments it appears that the author's coccobacillus may confidently be considered to be the causative agent of ozena.

Displacement of Peripheral Infiltrations Toward the Serous Cavities in Cirrhosis, Bright's Disease, and Heart Disease.—A. Lemierre and J. Lévesque (*Presse médicale,* May 2, 1923) discuss the factors other than gravity which influences the distribution of adematous fluid and serous effusions in these disorders. Potain, Huchard, and others long since taught that in cardiac cases transudations into the pleural or peritoneal cavities formed a kind of peripheral barrage or dam which hindered the action of digitalis and the removal of which by puncture was often followed by the onset of diuresis under this drug. The authors describe cases showing that these cavities at times actually attract serous accumulations in heart insufficiency or renal impermeability, and that paracentesis in such cases induces a mobilization of edema fluid and its return into the blood circulation by making use of the attraction for water and chlorides exerted by the serous membranes—generally diseased—which is greater than that exerted in the subcutaneous cellular tissues. For this reason the appearance of ascites or pleurisy in some cases of cardiac decompensation or nephritis with edema, refractory to heart tonics and diuretics, is a salutary complication, provided the observer takes care to avail himself of it by puncturing. By combining a salt free diet with repeated punctures, one may bring about not only temporary clinical improvement but a considerable prolongation of life, even where an early fatal termination had been expected. This procedure, when available, is certainly preferable to the measures for direct evacuation, such as blistering and Southey's tubes. As much puncturing as possible should be done before giving digitalis or theobromine. As long as serous effusions persist in any given case, the physician retains much power to reduce suffering and prolong life.

Experiences With Splanchnic Anesthesia.—Ernst Kutscha-Lissberg (*Wiener klinische Wochenschrift,* March 22, 1923) finds that, with practice, splanchnic anesthesia fails very rarely, but that complete anesthesia is not always accomplished even with practice. The surroundings of the splanchnic nerve seem to entail greater dangers than other regions. Not only an undesirably rapid resorption and resulting intoxication, but also an occasional prompt reflex collapse may occur and even secondary injuries in the sense of an atony of the stomach and intestine. Atropin, at least in a single injection, does not eliminate these injuries with certainty, but it does seem to render such occurrences to occur less frequently. Patients who show a labile balance relationship between the sympathetic and vagus nerves are endangered by splanchnic anesthesia. Future work along these lines must be directed toward eliminating these gross variations between the sympathetic and the vagus nerves.

Mass Treatment of Hookworm Infection.—K. S. Mhaskar (*Indian Medical Gazette,* June, 1922) treated 1,600 cases with thymol, 900 with betanaphthol, and 2,200 with chenopodium oil. His conclusions are that the chenopodium treatment is efficient, but toilsome, costly, and uncertain as to safety, while both thymol and betanaphthol treatments are efficient, simple and safe, one treatment being enough to reduce ninety-three per cent. of hookworm infection. Both thymol and betanaphthol are good anthelmintics possessing vermicidal and vermifugal properties. The maximum dose of each if fifty grains mixed with twenty-five grains of light magnesium carbonate, given without a purgative, and only one treatment is needed. The choice between the two drugs seems to be dependent on the price of each and thymol is very much cheaper in India.

Treatment of Laryngeal Diphtheria by Suction.—R. W. Grover and R. P. Hardman (*Archives of Pediatrics,* March, 1923) endeavored to lessen the number of cases needing intubation, and thereby lessen the mortality, by removing the membrane in laryngeal diphtheria by suction. The results are encouraging. The method used is by direct laryngoscopy, Boyce position, using either specially made metal tubes or silk elastic catheters and a motor driven suction pump. The danger of a false passage is exceedingly small, provided that the tube is introduced under ocular guidance when the larynx is open during inspiration. The entire procedure ordinarily takes only a few minutes and in the majority of cases the relief is immediate and marked. This treatment will not always obviate intubation or tracheotomy, but it will markedly lessen the number of cases requiring them and lessen the mortality.

Convalescence

following the acute infections, such as **influenza, pneumonia, bronchitis, diphtheria, scarlet fever and measles, as well as after surgical operations, child birth,** and so on, is rapidly promoted and hastened by the systematic use of

Gray's Glycerine Tonic Comp.

Two to four teaspoonfuls, three or four times a day, stimulate the appetite and aid digestion, thus increasing food assimilation and building up in natural ways, the vitality and strength of the body.

Thousands of busy practitioners turn to Gray's Glycerine Tonic Comp. whenever a restorative or reconstructive is needed, because their experience has shown them that it can be relied on to produce the results they seek.

Dysmenorrhea

is one of the most common and intractable affections that tax the skill of the practitioner. Fortunately, in

Hyperol

the practicing physician has a remedy that, owing its beneficial action to its regulation of the utero-ovarian circulation, promptly reduces the local congestion and thus effects an early relief from pain. Not the least, therefore, of the notable advantages of Hyperol, is the way it obviates, in the great majority of cases, any necessity for opiates or narcotic drugs, with their all too evident dangers.

But it is through its restoration of normal functions of the uterus and ovaries that Hyperol accomplishes its greatest benefits, for it thus enables medical men to produce results in **amenorrhea, dysmenorrhea, subinvolution and kindred** ills that are possible with few other remedies.

Valentine's Meat-Juice

In **Typhoid, Gastric** and **Other Fevers,** where it is **Essential** to **Sustain** the **Patient** without **Irritating** the **Weakened Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening** when **Other Food Fails.**

J. R. Wood, M. D., *Physician Sheltering Arms Hospital, Paint Creek, W. Va., U. S. A.:* "I have been using VALENTINE'S MEAT-JUICE in the treatment of Typhoid Fever cases in the Sheltering Arms Hospital, for the last two or three weeks, with the most gratifying results both to the patient and physician. I consider it the best preparation of animal food I have ever seen, in fact, the only one I have ever had any success with."

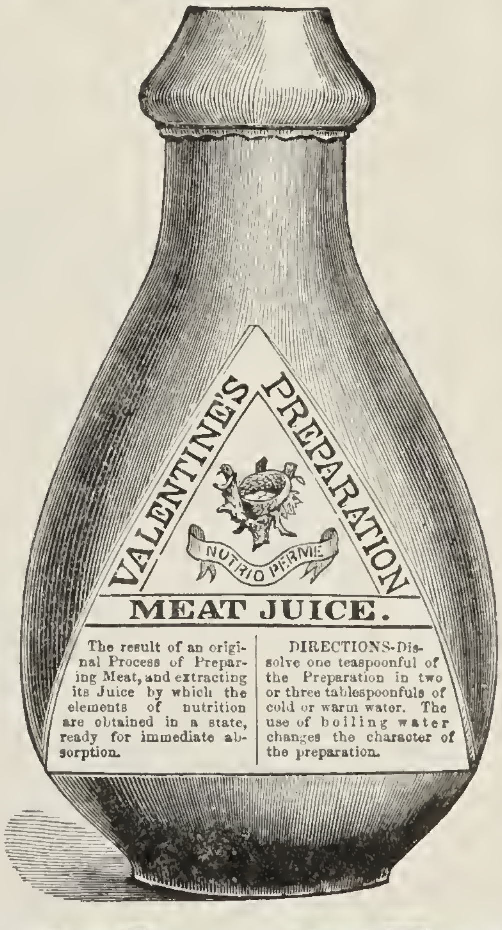
Dr. Genevaix, *Assistant Surgeon-Major, First Class, Hotel Dieu, Creusot, France:* "The patients to whom I have given the excellent preparation, VALENTINE'S MEAT-JUICE, have found their general condition rapidly improved by it, and in the convalescence from continued Fever (Typhoid and Para-Typhoid) it gives the best results."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,
Richmond, Virginia, U. S. A.

S 193



The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

What Conclusions May Be Drawn From the Demonstration of Colon Bacilli in the Stomach of Infants?—W. Grävinghoff (*Monatsschrift für Kinderheilkunde,* March, 1923) finds that bacteria of the colonlactis aerogenes group occur in a considerable number of stomachs of infants, which finding is a valuable support of the theory that the presence of colon bacilli in the stomach and duodenum is the usual associated finding in disturbances of the gastrointestinal canal. It is still a question whether they are the necessary prerequisite for the development of these disturbances.

Colon Bacillus Agglutinins.—Eugen Kramar (*Monatsschrift für Kinderheilkunde,* March, 1923) found that only five marked agglutinin values occurred among twenty infants that were inoculated. Infants less than one month old remained almost completely refractory. The ability to develop colon bacillus agglutinins is, therefore, only very moderately developed in infants, particularly in those less than one month old.

Studies on the Tuberculin Reaction and on Specific Hypersensitiveness in Bacterial Infection.—Hans Zinsser (*Journal of Experimental Medicine,* November, 1921) in summarizing his investigations states that the following points seem incontrovertible on the basis of his experiments, as well as those of other workers: 1. Two fundamentally different types of intradermal reactions may be observed in the guineapig. They are the immediate, transitory reaction, and the tuberculin type of skin reaction. The first is that which develops in animals sensitized against proteins (horse serum, etc.), and may be regarded as one of the manifestations of general hypersensitiveness or anaphylaxis; the second develops more slowly, leads to a more profound injury of the tissues, and is independent of anaphylaxis as commonly conceived. 2. The tuberculin type of hypersensitiveness (and also probably the typhoidin, mallein, abortin reactions, etc.) do not develop at all in guineapigs sensitized with proteins, such as horse serum. While this form of hypersensitiveness may eventually be induced with materials not bacterial in origin, it has been observed so far only as a reaction of bacterial infection. 3. Methods of treatment with protein material from bacterial cultures which sensitize guineapigs to anaphylactic reactions with the bacterial extracts, do not sensitize them to the tuberculin type of reaction. Such sensitization is easily accomplished only by infecting the animals with living organisms. No reliable method of sensitizing guineapigs to such reactions with dead bacterial material has as yet been worked out, though a few hopeful experiments have been obtained with massive injections of large amounts of the acid precipitable substances (nucleoproteins?) from bacterial extracts. 4. In animals made hypersensitive to the tuberculin type of reaction by infection with living bacteria, the reaction may be elicited by intradermal injections of bacterial extracts from which all coagulable proteins, nucleoproteins, and Bence-Jones proteins have been removed as well, as this can be done by boiling with acid, etc. This proteose residue alone suffices to elicit such reactions. The exact chemical nature of the socalled proteose residue must be further studied and analysed. Zinsser then presents a number of theoretical considerations which the experiments suggest, and states that if the deductions he makes have any value, the attention of bacteriologists should be turned to the nonprotein constituent of bacterial cells in their further immunological studies, as well as to the protein materials.

The Hydrogen Ion Concentration of the Blood in Carcinoma. I. From the Colorimetric Determination of the Blood Dialysate.—William H. Chambers (*Journal of Biological Chemistry,* February,1923) determined the hydrogen ion concentration of the dialysate from the venous blood in forty-five cases of carcinoma. At 20° C. it averaged 7.45, which was slightly more alkaline than that of normal subjects, 7.31. In general, the degree of alkalinity corresponded to the size and extent of the tumor growth, small growths without metastases showing little or no increase above the normal.

The Influence of the Sodium Ion in the Production of Tetany.—Frederick F. Tisdall (*The Journal of Biological Chemistry,* September, 1922) injected dibasic sodium phosphate and phosphoric acid into dogs intravenously, the time required for each injection being about one hour. The injection of the dibasic sodium phosphate caused twitching in all four dogs, although a condition resembling active tetany occurred in only one of them. After the injection of phosphoric acid no signs of increased irritability appeared. It is concluded that the sodium-calcium ratio is the important factor in the production of tetany, excepting the gastric type, and that the calcium-phosphorus ratio has no influence on the production of tetany. Gastric tetany is probably due to an increase of the bicarbonate ion, and not to a disturbance of the sodium-calcium ratio.

Action of Drugs on Respiration. I. The Morphine Series. Carl F. Schmidt and W. Benson Harer (*The Journal of Experimental Medicine,* January, 1923) performed the work described in order to ascertain whether drugs which are known to depress cough selectively have a more marked action on expiration than on inspiration. The cat was used for their experiments. Morphine and heroine were found to exert a selective depressant action on the central expiratory mechanism without producing narcosis, and often without depressing inspiration. Codeine had no constant effect except stimulation of the spinal cord.

Agglutinations of Dysentery Bacilli in Children.—Paul Widowitz (*Wiener klinische Wochenschrift,* March 22, 1923) concludes: 1. The formation of agglutinins against dysentery (Flexner-Y) assumes the presence of a dysentery infection, so that the socalled normal agglutinins should be considered to be a specific residual immune agglutinin. 2. The original infection, which in many cases of endemic dysentery affects children during the first year of life, leads to diminished agglutinating values, which are increased in their titre values by superinfection. 3. By the time that puberty has passed, most of the individuals have gone through an infection with this disease. Just as in tuberculosis, infection and disease should be differentiated. 4. The coagglutinins also presume the presence of an infection with the homologous bacterium.

In recommending an infant food
—consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

Schieffelin & Co.
NEW YORK

Influenzalike Bacilli.—T. M. Rivers (*Bulletin of the Johns Hopkins Hospital,* December, 1922) describes two influenzalike bacilli requiring the addition of only an autoclave-labile substance as an accessory food factor. For this group of organisms the name Bacillus parainfluenzæ or Hemophilus parainfluenzæ is suggested.

Observations on the Production of Toxic Substances by Pneumococci.—Alan M. Chesney and Alfred B. Hodges (*Bulletin of the Johns Hopkins Hospital,* December, 1922) discuss the relationship of the toxic substances obtained from pneumococci by solution of the bacterial cell or by manipulation of pneumonic exudates to the phenomena of intoxication in pneumonia in man. In no instance were any toxic effects observed in the mice injected intraperitoneally with filtrates of actively growing cultures of pneumoncocci in beef infusion broth, normal human serum and defibrinated normal human blood.

Loss of Circulating Erythrocytes in Certain Types of Experimental Pneumonia.—Chauncey D. Leake and Thomas K. Brown (*Journal of Experimental Medicine,* December, 1922) found a marked decrease in red cell counts of dogs with experimental pneumonia. The blood volume remaining constant, the hemoglobin fell in proportion to the fall in the number of red cells, and there was a marked increase in plasma with a corresponding fall in the mass of formed elements. Thus there appears to be an actual loss of erythrocytes in the effective circulation without a compensatory regeneration. Postmortem examination of the tissues of various organs showed the red cells in different stages of degeneration in the capillaries and tissue spaces of the lungs, liver, spleen and intestinal wall.

Microchemical Demonstration of Hydrocyanic Acid in Poisonings.—H. Brunswik and F. Neureiter (*Wiener klinische Wochenschrift,* July 13, 1922) report that the microchemical reaction for hydrocyanic acid which has been used to determine the presence of the hydrocyanic acid in vegetable matter can also be applied in medicolegal matters. The hydrocyanic acid is released by the addition of oxalic acid at room temperature and is used as an indicator with silver nitrate. Characteristic crystals of silver cyanate occur, which color "true" in the presence of methylene blue. With the aid of recrystallization, the crystals may be positively identified.

The Action of Drugs on Respiration.—Carl F. Schmidt and W. Benson Harer (*The Journal of Experimental Medicine,* January, 1923) report that with all the drugs tested—ether, chloroform, hydrated chloral, urethane, magnesium, and luminal—there occurred a more or less selective depression of expiration, as with morphine and heroine, but narcotic doses were required to produce any effect, and inspiration was always definitely depressed; expiration was weakened, but did not become passive until very marked depression of inspiration appeared. The effect of these various drugs is described. Caffeine and strychnine, whenever they caused acceleration after morphine, brought back active expiration. Atropine never stimulated, and commonly acted as a synergist to morphine. The authors suggest that the results outlined here and in the previous paper point to the existence of a separate central mechanism for the control of each of the phases of respiration, and that, while each responds to the same chemical stimuli, the threshold of the expiratory is higher than that of the inspiratory. Evidence is presented to indicate that if expiration remains passive a marked increase in depth of breathing may slow the rate, and a respiratory mechanism that lacks active expiration may be so inefficient that a CO_2 concentration which stimulated when expiration was active may depress when it is passive.

Spontaneous Pneumothorax in Infancy.—Bruno Schönfeldt (*Monatsschrift für Kinderheilkunde,* December, 1922) observed six cases of grippe pneumonia in children, ranging from seven months to four years of age. Spontaneous pneumothorax resulted in four cases (all fatal) and mediastinal and skin emphysema resulted twice (one fatality). The pneumothorax was produced twice as the result of rupture of the abscess into the pleural cavity, once as a result of the rupture of an emphysematous air space; the mediastinal emphysema was produced once as the result of the perforation of a bronchus lying in tuberculous infiltrated tissue. In one case of pneumothorax, emphysema could be made only with röntgenography.

Residual Nitrogen Values in Diphtheria and the Effect of Antidiphtheric Serum Upon the Disease.—Grete Glesinger-Reischer and Bernhard Glesinger (*Wiener klinische Wochenschrift,* March 8, 1923) found that as a rule a moderately increased residual nitrogen underwent a rapid diminution in about half the cases of diphtheria after a successful treatment with serum. On the other hand, a complication, such as, for example, scarlet fever or tonsillar abscess, or an incomplete effect upon the disease process from serum (persistence, of the fever and of the membrane) diminishes the reduction of the residual nitrogen and even causes an additional increase.

Rheumatoid Arthritis Treated With Intravenous Bacillus Coli Vaccine.—Rowland J. Perkins and G. Bruce White (*British Medical Journal,* March 10, 1923) assert that the intravenous use of Bacillus coli vaccine does appear to have a definite value, especially as an adjuvant to the more recognized methods of treatment. It is still too early to state whether any benefits that may have resulted are permanent. They consider this form of treatment to be indicated under the following conditions: 1, cases in which no definite focus of infection can be located; 2, cases in which the more recognized methods have failed; 3, early cases in which the process in the joints is still active, especially if swelling and effusion are present. Little can be hoped for when adhesions are present in the joints. A great difficulty in the execution of the treatment is the estimation of the proper dose of vaccine so as to produce a beneficial reaction which would not be too severe for the patient. The initial dose should be as large as possible. The reaction consists of a rise of temperature a few hours after the injection, frequently associated with a chill. Nausea and vomiting may also occur. The reaction usually lasts from twelve hours to two days. If improvement occurs at all it occurs usually within two days. The best results were observed in those cases which showed the severe reactions.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack. Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

135 Christopher St. **The Purdue Frederick Co.** New York

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **General Debility** with **Impaired Digestion** of **Phthisis,** and in the **Depressing Prostration** following **Influenza** it is recommended by many practitioners throughout the world as invaluable in their treatment.

Phthisis.

J. Mertens, M. D., *A. T. O. Bristol Municipal Tuberculosis Dispensaries, Bristol, England:* "I am pleased to state that the results obtained from VALENTINE'S MEAT-JUICE were very satisfactory indeed in all cases where no other kind of food could be used. It produced excellent results with wounded soldiers suffering from Tuberculosis of the lungs."

Dr. Gouel, *Physician in Chief Villepinte Hospital for Consumption, Paris, France:* "VALENTINE'S MEAT-JUICE succeeds well in cases of Anæmia and in the treatment of Tuberculosis in an advanced stage when the stomach is intolerant."

Physicians are invited to send for brochures containing clinical reports.

MISCELLANY.

Ether Oil Rectal Anesthesia to Produce Twilight Sleep.—H. Thaler and R. Hübel (*Zentralblatt für Gynäkologie,* March 3, 1923) were enabled to produce a condition resembling twilight sleep in pregnant women with the use of a slow rectal administration of one hundred c. c. of a freshly prepared ether oil mixture (ninety gm. pure sulphuric anesthetic ether and 120 gm. of the purest olive oil), which condition was particularly characterized by postpartum amnesia. States of excitation, such as are produced by scopolamine anesthesia, were never observed. The intestine showed absolutely no irritative conditions. Among one hundred observations, the course of the labor was normal eighty times and slightly weakened twenty times. Only two infants showed typical asphyxia, one of which died. This form of anesthesia should be used only in hospitals.

Inflammatory Adnexal Tumors as a Complication of Pregnancy.—George Richter (*Zentralblatt für Gynäkologie,* March 10, 1923) shows that active intervention as early as possible is necessary in every case of inflammatory tumor complicating pregnancy. Even though the pregnancy is far advanced, operation on the adnexa in pregnancy is generally well borne and the pregnancy need not necessarily be interrupted as a result of the operation. However, even if the pregnancy is interrupted, such an occurrence would be less dangerous than abortion in the presence of an infection. Laparotomy is nearly always necessary, the vaginal route may be employed in cases of abscesses and pyosalpinx accessible from the posterior fornix, but the danger of ascending intrauterine infection and sepsis is imminent. The extirpation of the pregnant uterus, together with the tumor, leaving intact, if possible, the ovary on the opposite side, the author regards as the method of choice. Mere extirpation of the infected adnexa containing pus may be dangerous.

Active Rotation of Fetus After Version From the Dorsoposterior Transverse Presentation.—In those severe cases, in which with dorsoposterior transverse presentation the anterior foot cannot be grasped, but one must be satisfied in grasping either foot of the fetus, and in cases in which the lower foot has been chosen instead of the upper foot and the sacrum has lodged behind the symphysis with the attempt at extraction, Friedrich Heinlein (*Zentralblatt für Gynäkologie,* March 10, 1923) calls attention to the fact that the textbooks recommend that under such conditions extraction should not be proceeded with immediately, but a labor pain should be awaited or should be replaced by pressure from without, so that the extremity lying posteriorly should turn toward the front spontaneously. In the cases in which such a turning does not occur the author was repeatedly enabled to accomplish the turn by traction on the leg laterally and anteriorly; but the traction and the turning must be done simultaneously, so that the femur is not fractured. The direction of the turning must be the same as that toward which the toes of the fetus point. The back then travels posteriorly, but only transiently and glides past the promontory. In this respect there need be no fear of the version of the fetal back posteriorly.

The Widal (Hemoclastic Crisis) Functional Liver Test in Pregnancy.—G. Kaboth (*Zentralblatt für Gynäkologie,* November 25, 1922) found that the Widal functional liver test is not applicable as a test of pregnancy. The hemoclastic crisis certainly appears much more frequently in pregnancy than in normal persons, but the test also results positively in infectious diseases, inflammations of the adnexa, appendicitis, after chloroform and ether anesthesias, which renders this test unfit as a test of pregnancy.

Puerperal Occlusion of Mesenteric Vessels and the Etiology of Common Thrombosis.—Bucura (*Wiener klinische Wochenschrift,* November 23, 1922) states that the thrombosis of the superior mesenteric artery is extremely rare in the puerperium. The author does not believe in the etiological effect of the retardation of the blood stream, which is generally assumed at the present time. He asserts that this may favor the increase in size of the thrombus, but for its origin there must be present a hypothetical change in the vessel wall (possibly also a change in the blood), as a result of which the circulating toxins enter the organism during pregnancy. It is for this reason that exercises in the bed, early leaving the bed, etc., cannot prevent the formation of thromboses. An attempt should be made to paralyze the toxic effect by early prophylactic measures, for which purpose proteotherapy, vaccinotherapy, the administration of endocrine extracts, the regulation of the intestinal activity and of the renal function, sweating procedures, etc., may be used. If possible, mesenteric thrombosis should be attacked surgically.

Influence of the Treatment of Syphilitic Pregnant Women Upon the Incidence of Congenital Syphilis.—J. Whitridge Williams (*Bulletin of the Johns Hopkins Hospital,* November, 1922) analyzed 113 pregnancies occurring in ninety-six women during two years, nine of which ended in abortion and six in premature labor, all the latter patients dying. The treatment of the women was classified under five heads, groups A to C being composed of those women who received sufficient treatment, so that the Wassermann reaction remained negative for one year in the first class, and three months in the third class, after the cessation of the last treatment; Group D comprised those in whom the Wassermann became negative only shortly before the birth of the child, and Group E, all those in whom the treatment was notoriously insufficient. Of the ninety-eight children, four died from accidents of labor. The remaining children were followed and notes made on their condition from four to twenty-eight months after birth. The results showed that of the ninety-four children who were born alive five, or 5.3 per cent., showed demonstrable evidence of syphilis, while seventy-six were living and well, nine had been lost track of, and four had died. This study indicates that almost ideal results follow anything like efficient treatment of syphilitic pregnant women, and that surprising results sometimes follow what would be ordinarily considered altogether inefficient treatment in men or nonpregnant women, which would seem to indicate the pregnant women are usually amenable to antisyphilitic treatment.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

NEW YORK

A New Method of Inducing Labor Pains.—Paul Klein (*Zentralblatt für Gynäkologie,* August 12, 1922) observed that strong labor pains usually set in after the repeated rectal examination of pregnant women. This reaction he attributes to the stimulation of the Frankenhäuser ganglia and he utilized this in a practical manner in the treatment of weak labor pains. A rubber balloon is placed in the rectum and filled with 100 to 250 c. c. of water. This procedure he calls procteurysis; it is just as reliable as colpeurysis. It is absolutely painless and harmless and is easily borne by the pregnant woman. Its chief advantages are: 1, the rapid development of powerful labor pains, which recur at regular intervals; 2, a rapid disappearance of the vaginal portion of the cervix, owing to the effect of the pressure and its special applicability in primiparæ; 3, the extragenital introduction of the balloon, thereby preventing the introduction of infection into the genital tract or an ascent of the germs into the genital tract alongside of the balloon; 4, the promotion of the flow of the secretion outward, as a result of the stretching of the posterior vaginal wall and of the posterior fornix becoming shallow; 5, the easy technic—the balloon, fluid and the physician's hands need not be sterile; 6, the sparing of the balloon because it need not be boiled before each introduction; 7, spontaneous micturition is possible.

Indications in the Treatment of Febrile Abortion From the Bacteriological Viewpoint.—W. Sigwart (*Zentralblatt für Gynäkologie,* September 23, 1922) asserts that the bacteriological investigation of the secretions from the uterus will never give decisive information upon which the therapeutic measures may be based until we have learned to differentiate absolutely between virulent and avirulent streptococci. The fact that the streptococci found in any secretion produce hemolysis is immaterial as regards methods of treatment.

Value of Blood Pressure Determinations in the Renal Disturbances of Pregnancy and Labor.—W. Gessner (*Zentralblatt für Gynäkologie,* October 28, 1922) states that a fall of the blood pressure in the puerperium is the result of toxins, that it is an important sign in prognosis, and that it acts as a danger signal for the institution of supportive treatment for the heart and vascular system. A rise in the blood pressure in pregnancy, on the other hand, is produced not only by injury of the kidneys, but, according to the author, by a simple increase in the intraabdominal pressure as a result of the enlargement of the uterus; such an increase in blood pressure may exist with a kidney of pregnancy.

Wassermann and Meinicke Reactions in Carcinoma of the Uterus.—Robert Niedermayr (*Wiener klinische Wochenschrift,* January 4, 1923) found one cachectic case with a positive Meinicke reaction and a weakly positive Wassermann test with inactivated serum among twenty-five cases of carcinoma of the uterus; one case revealed a positive reaction after röntgen irradiation. He concludes that these two tests cannot be utilized with any certainty in the differential diagnosis between uterine hemorrhages of a syphilitic or carcinomatous nature. These tests are not positive more often in advanced carcinoma, recurrences, and after intensive röntgen irradiations, in which cases a marked blood toxicosis has resulted from resorption of carcinomatous tissue, as would naturally be expected. There are even cases, in which the slight reaction present previously to the irradiation has entirely disappeared after it. Owing to the scarcity of such cases, the determination whether the appearance of the reaction after the irradiation is due to the irradiation or other causes (advancing cachexia?) is difficult.

Proposals for the Protection of the Ovaries During Postoperative Irradiation.—Walter Offermann (*Zentralblatt für Gynäkologie,* April 21, 1923) asserts that during postoperative irradiation after the extirpation of a cancer of the uterus insufficient attention is paid to the function of the ovaries and as a result the ovaries are destroyed. After vaginal or abdominal hysterectomy for a malignant growth the author recommends cutting the ovary into discs from one to two millimetres thick and inserting them singly at various points between the rectus muscle and its anterior sheath. The area just above the umbilicus is the best, as a wide area is thus left free for irradiation. The ovaries are safely protected from the effects of the irradiation and can then be protected by lead plates. This procedure will guarantee the continuance of ovarian function for a period of three to five years, until the body is able to become accustomed to the loss of the ovarian function. Mild symptoms of loss of ovarian function usually appear for three or four months after the operation until the transplanted ovary becomes established in its new location. Another procedure is to transplant one ovary and leave the other in place.

Rodent Ulcer of the Vulva.—Friedrich Jess (*Zentralblatt für Gynäkologie,* March 31, 1923) states that the differential diagnosis between rodent ulcer and soft and hard chancre and tuberculous and carcinomatous affections can be definitely established only by a process of exclusion. Contrary to the prevailing opinion, it can be treated not only surgically but also conservatively. A case is reported in which general treatment with iron and arsenic, as well as cauterization with carbolic acid, silver nitrate and tincture of iodine, produced a cure within six months. Special emphasis is attached to the general condition of the patient and the general treatment. Individuals in a reduced and poorly nourished condition, especially those suffering from consuming diseases, are peculiarly predisposed to obstinate, nonspecific ulcerations on the external skin and the external genitals. Such individuals should be subjected to operation only when intensive and long continued general treatment and the healing of any other disabling condition present have made them fit for operation.

Treatment of Puerperal Infections.—B. P. Watson (*British Medical Journal,* March 24, 1923) believes that curettage or any intrauterine manipulation should never be done in a case of abortion showing a rise of temperature, except in the presence of severe hemorrhage. If in incomplete abortion a mass is felt blocking the cervical canal, nothing more should be done than to remove it carefully. A gentle curettage may be done after the temperature has subsided to normal for several days, if the bleeding persists and if the cervix remains patulous. Even then there may be evidence of a blood invasion, as shown by a rise of temperature after the operation and occasionally by a chill.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

VALENTINE'S PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY.

Gangrenous Dermatitis Following Appendectomy.—Marshall Clinton (*Bulletin of Buffalo General Hospital,* April, 1923) reports a unique complication in abdominal surgery. Following the removal of a gangrenous appendix, which was walled off as usual, there developed a rapidly progressive necrotizing process affecting all the layers of the skin and involving in a short period almost the entire abdominal wall. Associated with this there was a considerable constitutional reaction which threatened the life of the patient. The process lasted five weeks before any signs of abatement set in. There was little proof that the process was due to infection despite the several varieties of bacteria that were isolated. The infection of the laparotomy wound could very well have been secondary to a beginning necrosis of the skin in that locality. Other possibilities of causation are local circulatory disturbances —embolic, thrombotic, or endarteritic—for none of which there was any evidence. Nor was there any evidence of a neurotic skin gangrene. On the other hand, it is difficult to regard the appendectomy as a mere coincidence. There need not, however, be a direct infection but perhaps some mechanical effect upon the local circulation, or, possibly, some traumatic, infectious or toxic effect upon the nerve supply, with a resulting neuritis and trophic disturbance in the skin of that region.

Effect of Fat Upon the Assimilation of Sugar. Kozo Sakaguchi, Osamu Asakawa and Satosu Nakagawa (*Mitteilungen aus der Medizinischen Fakultät zu Tokyo,* Band xxix, Heft 2) report: 1. That both in the nondiabetic as in the slightly diabetic individuals the hyperglycemia, which occurs after the ingestion of a carbohydrate diet, is more or less diminished by the abundant addition of fat, although the effect is often insignificant. Accordingly the glycosuria under such conditions is frequently observed to be somewhat less than without the addition of fat. This reduction of the glycosuria by the fat varies in strength in different cases. At any rate the addition of fat in slight diabetes has no injurious action on the glycosuria, as long as a carbohydrate diet is consumed. However, in patients with intestinal catarrh, the fat, in addition to the aggravation of the diarrhea, may also reduce the assimilation of sugar. 2. If sufficient fat is added to a strict diet in a severe case of diabetes, the increase in the glycosuria appears to occur in every case. 3. The injurious effect of the fat upon the tolerance, as well as upon the acidosis, varies with the addition of like amounts of fat: the "sensibility to fat" varies in individuals. 4. Although the increase in glycosuria occurs usually only with large additions of fat, nevertheless the "sensibility to fat" often appears to occur even with such amounts of fat as are used in the practical treatment. 5. The injury to the tolerance by the administration of fat is always associated with a distinct increase in the acidosis and both seem to stand in an intimate relationship. The continued injury to the tolerance appears only in the cases in which the acidosis rises continuously by the administration of fat. Where the originally increased acidosis begins to diminish after a few days on the continuation of the same diet, the tolerance is injured only for a short time and may even be absent entirely. 6. The appearance of sensibility to fat seems to depend upon the fact that the increase in acidosis as a result of the administration of fat also injures the assimilation of sugar. 7. Inasmuch as the diminution of the tolerance occurs only with the administration of large amounts of fat and with an increased acidosis, the injury of the tolerance in most of the cases may be avoided by regulating the administration of fat according to the finding of the acidosis, as is usually done today. Also in cases, in which the increase in glycosuria is observed as a result of the administration of fat, it is proper to determine first the lower limit of the injurious amounts of fat in a particular case and then to limit the administration of fat to such an extent that it does not overstep these bounds. A marked restriction of the fat does not appear to be justified.

Two Cases of Idiopathic Type of Osteopsathyrosis Associated with Congenital Syphilis.—Prescott Le Breton (*Bulletin of Buffalo General Hospital,* April, 1923) presents two cases showing a combination of congenital syphilis with changes in the osseous system corresponding in its most important features with idiopathic osteopsathyrosis. As regards the relation of the two conditions to each other, it will hardly be determined on clinical evidence alone. Generally, syphilis is denied any causative rôle in osteogenesis imperfecta or osteopsathyrosis, although cases of possible syphilitic origin have been reported. However, since so little is known regarding the etiology of osteopsathyrosis, it may be possible that it is not due to one sole cause but that several different agencies including syphilis are capable of producing similar bone lesions. This is especially true since the cause or causes may only be operative through the endocrine system, as has often been postulated.

Should a Suppurative Adnexal Tumor Be Operated Upon or Not?—George Katz (*Zentralblatt für Gynäkologie,* June 10, 1922) asserts that the modern view as to whether suppurative adnexal inflammations should be treated conservatively cannot be precisely stated, although the differences of opinion on this subject are not so divergent as formerly, which is partly due to the modern improvements in surgical technic. As a result of successful operations in three cases of acute and fresh exacerbating adnexal inflammatory tumors, the author advocates surgical intervention. The patients operated upon were all ill for a long time and were subjected to more or less intensively conservative treatment and the laparotomy was done as a last resort. The generally accepted rule of operating only during an interval of the chronic stage and in the subacute stage was disregarded. Although it is often possible to relieve fresh or recurring adnexal tumor cases with conservative measures within four to six weeks, nevertheless there is no anatomical restitution; the pus in the tubes may become inspissated and shrinkage may result, but the adhesions with the resulting displacement of the uterus remain, only to give renewed trouble later on, even though there may be no acute exacerbation. The conservative treatment with terpichin failed in the hands of the author and even aggravated the condition, so that operation had to be done eventually as a lifesaving measure. The social aspect should also be given consideration so that the quickest results may be obtained.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

Treatment of Sterility in the Female.—Erwin Graff (*Wiener klinische Wochenschrift*, January 25, 1923) thinks that the examination of the semen from the vagina is preferable to the usual condom method. Primary sterility usually shows hypoplasia of the sex organs, for which mechanical therapy (dilatation of the cervical canal) has been replaced by etiological therapy. This condition may be evidenced merely by irregular menstruation. Menstrual disturbances that indicate ovarian disturbances are relieved by röntgen therapy and ovarian therapy. Sterility may be caused by posterior displacements of the uterus, though their influence is largely overestimated. Inflammatory conditions in the genitals require treatment and the determination whether the tubes are patent is important. Gonorrhea frequently causes sterility. If the patency of the tube is established by Rubin's test, operation is indicated. Conservative treatment very often suffices to bring about pregnancy. The author is a believer in the theory of an immunity against semen and he does not consider dyspareunia a bar to sterility.

Significance of Varicocele in Women.—Gotthard Schubert (*Zentralblatt für Gynäkologie*, October 14, 1922) considers varicocele of the broad ligament as a disease which may produce severe symptoms. Any treatment other than operation is useless. Only operative treatment comes up for consideration in the majority of the cases, inasmuch as the true cause, or the seat of the trouble, is only truly recognized at the time of the laparotomy. The technic of the operation should be individualized according to the nature of the case. The author considers the extirpation of the dilated plexus of veins in the mesosalpinx as entirely adequate for the extirpation of the superior parovarian varicocele. The removal of the internal genitals, together with the removal of the body of the uterus, should be reserved for only the most severe cases, inasmuch as the symptoms of artificial menopause, which may ensue, are just as unpleasant as the condition itself. Even the leaving of one ovary does not always protect against the symptoms of the artificial menopause, as the author saw some very severe symptoms following the vaginal extirpation of the uterus, even though both ovaries were left behind. Among thirty cases, the operations gave very satisfactory results in all but four.

Therapeutic and Prophylactic Injection Around the Nipple with Quinine.—Hans Kritzler (*Zentralblatt für Gynäkologie*, May 20, 1922) reports a case of unusually severe inflammation of the nipple, resulting from fissures during the puerperium. Both nipples were as large as half a prune, showing deeply penetrating, ugly looking, fissured ulcerations. The breasts were not infected. The condition failed to respond to every form of treatment and was excruciatingly painful. The author then tried nipple anesthesia with 0.5 per cent. quinine dihydrochloride carbamide, injecting the right nipple subcutaneously outside of the areola and around the left areola intracutaneously in the form of a wheal, so as to determine whether the intracutaneous or the subcutaneous nerves were responsible for the pain. On the left side the surface anesthesia was complete, whereas it was incomplete on the right side; the left side still showed deep seated pain, but the subareolar area on the right side was absolutely painless. Within twelve to twenty-four hours the swelling of both nipples receded entirely, showing a regular form and size, with the ulcerated areas completely united. The improvement from day to day was miraculous. Cauterization with ten per cent. silver nitrate solution was repeated once and the woman was discharged after four days. After another four days, the fissures were painless, almost cured, and the nipples appeared normal. The inflammatory condition was undoubtedly influenced by the disinfecting action of the quinine. The advantages of the nipple anesthesia with quinine are: 1, its simplicity; 2, the relief from excruciating pain, especially in nervous women; 3, it aids in the cure of the socalled paradoxic hypogalactia; 4, it prevents psychogenetic hypogalactia; 5, it aids milk production and secretion; 6, it favors the prevention of mastitis.

Relationship of Iodine Therapy of Arteriosclerosis to the Clinical and Pathological Aspects of This Disease.—After a careful analysis of the pathological anatomy and the clinical study of arteriosclerosis as well as the hemodynamic effect of the iodine, J. Wiesel (*Wiener klinische Wochenschrift*, April 9, 1923) comes to the conclusion that the iodine treatment has a particular effect on all the manifold phenomena underlying this process. If improvement in the condition is possible, it is due to the particular peculiarities of the disease process. In this way the cerebral arteriosclerosis is favorably influenced because the disease process in the cerebral vessels completely resembles that of syphilitic endarteritis. Improvement is to be expected to just as great an extent in arteriosclerosis which is produced by hyperthyroidism. The byeffects of the iodine in some patients must be warned against as these are frequently mistaken for signs of progressive arteriosclerosis, such as emaciation.

Effect of Camphor on the Lactating Breast.—J. Rosenblatt (*Zentralblatt für Gynäkologie*, September 21, 1922) reports that the administration of camphor inhibits the secretion of milk in the lactating breast, as would be indicated in cases of tuberculosis, decompensated heart conditions, etc., or after an infant has died and lactation is no longer necessary. Camphor is given internally for three to five days in doses of 0.12 to 0.18 gram three times a day, but subcutaneous injections of camphor produce results more quickly. The same effect may be obtained in cases of infants with lactating breasts, in which cases 0.01 to 0.02 gram camphor or compresses of camphorated oil are used. The results in a series of fifteen hundred cases were so strikingly good that all other methods of treatment have been abandoned by the author.

Indication for Ventrofixation of the Uterus.—Emil Ekstein (*Zentralblatt für Gynäkologie*, June 24, 1922) maintains that, inasmuch as the patients which he saw after having unilateral operations done on the adnexa (oophorotomy, salpingooophorectomy, extrauterine pregnancy, etc.) were suffering with a movable retroflexion of the uterus with its associated symptoms, which might have been avoided by a primary operation for the purpose of doing a profixation of the uterus, he ought to call attention to this indication for ventrofixation, more properly called profixation.

MISCELLANY.

Heating of the Tissues of the Body by Light and Heat Rays.—Leonard Hill and J. Argyll Campbell (*Lancet,* April 14, 1923) found that: 1. Exposure of the whole body of a rabbit to the sun's rays rapidly increased the temperature of the deeper tissues, the fur temperature rising as high as 54°C. 2. Exposure of the head and upper part of the body to the sun's rays was followed by a fall of temperature in the deeper tissues, the fur temperature in the sun not exceeding 46.5°C. 3. Local exposures of the head of a rabbit to the carbon greatly increased the temperature under the scalp and in the brain, the fur temperature rising above 60°C. The body temperature (rectal) was often not greatly altered. The respiration was always rapid (over one hundred a minute). 4. Even though it is recognized that heat stroke is usually due to a general raising of the body temperature, the results show that local heating may occur, and confirm the utility of pitch helmets and spinal pads on exposure to tropical sun. 5. Using the skin of the human knee and ordinary sources of rays (carbon arc and gas radiators) it was confirmed that luminous rays heat up the subcutaneous tissues to a greater degree than do nonluminous rays, the skin temperature being the same in both cases.

Application of the Test of the Rapidity of the Sedimentation of the Erythrocytes in Gynecology.—E. Rumpf (*Zentralblatt für Gynäkologie,* July 29, 1922) draws the following conclusions regarding the value of the erythrocyte sedimentation test in gynecology: The test for the rapidity of the sedimentation of the erythrocytes is a good means of determining the most suitable time for instituting active therapeutic measures (massage, curettage, operations on the adnexa, etc.). Sedimentation values below ten mm. in one hour allow the definite exclusion of inflammatory processes and the fairly certain conclusion that virulent germs exist in pus foci. The reaction has less value in differential diagnosis, as its greatest value lies in a negative result (below ten mm. an hour) and not at the height of sedimentation. Consequently, this test is serviceable in the differentiation of inflammatory organic processes from those produced by functional conditions. A normal rapidity of sedimentation of the erythrocytes does not speak against carcinoma and carcinomatous recurrences. The sedimentation test may have a prognostic value in blood transfusions.

Blood Platelets and Menstruation.—R. Pfeiffer and Hoff (*Zentralblatt für Gynäkologie,* November 4, 1922) show that on the first day of menstruation there is an extraordinary reduction in the thrombocytes from a half to a quarter and even to one fifth of the normal number. There seems to be a constant relationship between the large and small blood platelets. The number of the former increases constantly up to one or two days after the completion of menstruation. This phenomenon is explained by the fact that possibly the maturation of the ovarian follicle and formation of the corpus luteum acts on the spleen in such a manner that there is a hindrance to the extrusion of the thrombocytes from its sites of development in the bone marrow, or it may obstruct their rapid subsequent formation.

Experimental Hyperfeminism.—Josef Bondi and Rudolf Neurath (*Wiener klinische Wochenschrift,* June 8, 1922) report on their experiments, in which they implanted ovaries from nongravid donors into female rats of the same species and of the same age. Their aim was to produce a hyperfeminism but in only three out of twenty-seven cases did pregnancy result. This occurrence may possibly be explained by the fact that the uterus remains undeveloped. The authors have in mind an inhibitory effect of the changes in the transplanted ovaries upon the ovarian hormones, which also regulate the normal development of the uterus.

A Case of Adnexal Hernia.—Adolf Birmann (*Wiener klinische Wochenschrift,* June 29, 1922) reports a case in a woman who had a left sided hernia for many years which caused no inconvenience until it suddenly emerged during a defecation. It was replaced with difficulty and resulting continuous pain. After a time it emerged again and could not be replaced. After using forceful taxis, the hernia was finally reduced but caused a sudden severe pain in the left hypogastrium. The left side of the abdomen was rigid, the left inguinal ring was patent, and it contained an adherent mass. A reduction *en bloc* of the hernia was suspected and an operation under local anesthesia was undertaken. On opening the hernial sac, much blood poured forth and an inserted finger entered into a ruptured fallopian tube which contained a well preserved ovum about four weeks old. Extirpation of the tube resulted in recovery. The fallopian tube was probably pushed into the hernial ring during the act of defecation and became incarcerated there. Subsequently, the tube was ruptured by the forced taxis, resulting in hemorrhage into the peritoneal cavity and severe pains. Four similar cases were found in the literature, making this the fifth.

Simple and Effective Method of Administering Anthelmintics.—W. Horsley Gannt and Paul Foreman Wiest (*Therapeutic Gazette,* July 15, 1922), describe their method to be as follows: For at least twenty-four hours before administering anthelmintics, the patient is starved or allowed nothing but tea, coffee, and bouillon. The same evening, a dose of one ounce of magnesium sulphate is given, followed in two hours by a high soap suds enema. On the following morning, a second enema is given. The duodenal tube is then inserted into the stomach, with the patient on his right side, swallowing or sipping water frequently to induce the passage of the tube to the seventy-five cm. mark. This takes from twenty to forty minutes. In order to determine whether the tube has entered the duodenum, aspiration is done when a light golden yellowish fluid appears. When the tube is in the duodenum, fifteen c.c. of the following is inserted every fifteen minutes for four doses: ten c.c. of oleoresin Aspidii in mucilage of acacia sufficient to make sixty c.c. Two hours after the last dose, one and a half ounces of magnesium sulphate is given through the tube, which is then withdrawn. If the bowels do not move within four hours, the dose of salts is repeated and a saline enema administered. The method obviates discomfort, nausea and repetition of treatment, and ensures closer contact of the anthelmintic with the head of the worm.

Bowel Torpor in the Elderly

is usually the result of a progressive atony of the bowel, with a gradual decrease of the natural mucus and other secretions. The loss of moisture dries the feces and interferes with their free and easy passage. Under such conditions

INTEROL

serves as a safe and efficient substitute for the physiologic secretions. Following its systematic use, the bowel contents are kept soft, the intestinal canal—especially the large intestine—is adequately lubricated, and the feces are passed along and evacuated in due time without straining, pain, or discomfort.

INTEROL thus constitutes an ideal medium for the relief of bowel torpor in patients of advanced age.

DIRECTIONS:
In treating the elderly, begin with a tablespoonful morning and night on an empty stomach, increasing or decreasing as conditions require.

Sample and Interol brochure on request.

BACTERIOLOGICAL LABORATORIES OF
G. H. SHERMAN, M. D.
14600 E. Jefferson - DETROIT

Menorrhagias of Puberty.—L. Soler y Soto (*Revista Ibero-Americana de Ciençias Médicas*) says that menorrhagia due to a single gland is a rarity. Irregularities, like the normal functioning, of the reproductive system are under the control of a combination of endocrine glands. The thyroid body, the pituitary, and the suprarenal glands exercise an undisputed effect on the evolution and function of the genital apparatus, and it is a disturbance of their equilibrium that almost invariably causes irregular action on the part of that apparatus. The different degrees, therefore, of hyperfunction and hypofunction in one or other gland are of the greatest significance in the treatment of menorrhagia and similar conditions. Thyroid extract is appropriate in the first place for the known influence of that gland on the ovary; pituitary extract in response to important indications; hepatic extract, whose use in practice has been until now greatly limited; adrenal extract in the form of adrenalin; mammary extract, well known for its hemostatic effect; and ovarian extract. Most menorrhagias at puberty, unless due to genital displacement or to psychoneurosis, result from some blood dyscrasia; and the treatment most frequently found availing in correction of such a dyscrasia is the use of thyroid and pituitary extracts.

Peptone Immunization in Asthma and Other Allergies.—A. G. Auld (*Lancet,* April 21, 1923) states that in the clinical examination special attention should be given to the teeth, nasal cavities, tonsils, or other sources of infection; to the state of the lungs, the circulation, and digestion; to the presence of the gouty or rheumatic diathesis; and to endocrine defect. Operations for nasal affections sometimes aggravate the asthma. It is better to treat cases urgently requiring such at first, and then to wait some time before beginning the immunization. The skin tests may give valuable information. The patient usually knows what articles of diet to avoid; as the peptone treatment usually overcomes the sensitiveness to them it is often unnecessary to insist on their avoidance. The diet should be plain, very moderate, and diuresis encouraged by drinking water or soda water. In cases where dermal reactions to protein are given, the peptone acts more rapidly and often more effectually. After the constitutional symptoms have subsided, these reactions persist in the skin. Otherwise the desensitizing effect of peptone is universal and includes bacterial intoxication. Asthmatics are often highly sensitive to vaccines and the symptoms may be intensified by them. A five per cent. solution of peptone in physiological salt solution is used for intravenous injections and a seven and one half per cent. solution for intramuscular injections. They must be very carefully prepared and sterilized by heating up to 60° to 65° C. and then made faintly alkaline by soda or borax, the latter acting also as a preservative; otherwise one half of one per cent. carbolic acid is used. The injections are given slowly to avoid reactions, and are never given during the attacks. The dose is 0.3 c.c., increasing it by 0.2 c.c. up to 1.5 c.c. or more. When an attack occurs during the treatment, one must wait until recovery is complete, and then begin again with a very small dose, as the result of the attack is to produce the protective substance, antianaphylatoxin. The latter substance is also produced by a single big dose of peptone, but the protection is fleeting. On the other hand, the gradual immunization by small doses creates in addition that disorientation of the sensitized tissues toward the exciting agents which renders their attacks abortive for a longer or shorter time, according to the nature of the case.

Scientific Classification of Chronic Arthritis.—The following new nomenclature for the types of chronic arthritis is suggested by A. G. Timbrell Fisher (*British Medical Journal,* July 21, 1923): Chronic arthritis (monarticular, polyarticular); 1, synovial type (socalled rheumatoid arthritis), in which the disease commences and remains more marked in the synovial membrane, the cartilage and bone may be invaded secondarily, and every gradation may be seen between the chronic types and the more acute forms which lead to ankylosis; 2, chondroosseous type (socalled osteoarthritis), in which the disease commences and remains more marked in the articular end, the synovial membrane being involved later; 3, the mixed type, in which the disease commences simultaneously in synovial membrane and articular end and the changes advance *pari passu.* In all three types osteophytes may form at the articular margins, but in the synovial type they occur comparatively late in the disease, and in the more chronic forms which lead to ankylosis are usually absent. The suggested nomenclature is obviously only a primary classification. It is probable that further research will justify a subdivision of each type.

Influence of Sodium Salicylate Upon the Arthritis of Rabbits Inoculated With Nonhemolytic Streptococci.—Homer F. Swift and Ralph H. Boots (*Journal of Experimental Medicine,* April, 1923) inoculated rabbits with streptoccoci, giving one group sodium salicylate before the first inoculation as well as after. The animals receiving salicylates succumbed much more quickly to the streptococcus infection than did the controls. They developed almost as many inflamed joints as the untreated controls similarly inoculated. But the salicylated rabbits had a much higher proportion of mindly inflamed joints than the controls. The antiinflammatory action was most evident in animals inoculated with streptococcus of the lower virulence, and could not be demonstrated in animals inoculated with hemolytic streptococci.

Action of Sulphur.—A. Hottinger (*Schweizerische medizinische Wochenschrift,* April 26, 1923) emphasizes the following facts: 1. Sulphur is reduced to sulphuretted hydrogen in the intestine. 2. Sulphuretted hydrogen binds sulphur to the polysulphides. 3. Polysulphides, and particularly sodium polysulphides, transform themselves into each other and readily give off sulphur. 4. Biologically, sulphur acts as a hydrogen acceptor inasmuch as it reduces itself to sulphuretted hydrogen. In this way it appears to play an important part in oxidation processes in the organism, especially in the decomposition of certain acid products of metabolism. 5. Sulphuric acid forms readily from sulphuretted hydrogen under reduction of the blood hydrogen. 6. As a result, sulphur plays a double part in metaboism: as an oxidizing and a reducing substance.

"When Winter Comes"

—a great many patients—especially the weak and debilitated—need to be fortified against the depressing effects of cold weather, and for this purpose probably no remedy is more widely employed by physicians of experience than

Gray's Glycerine Tonic Comp.

If its use is started early, as soon as the chilly days of Fall begin, this tonic reconstructive will, in the great majority of cases, promptly raise the functional activity of vital organs, and as a logical sequence, produce a marked gain in the defensive powers of the body against germ attack.

Gray's Glycerine Tonic Comp. will thus enable the practitioner to carry many a patient through the Winter with gratifying freedom from the colds, coughs and catarrhal affections in general, that make this period so trying and dangerous to those susceptible to the acute infections.

Valentine's Meat-Juice

The **Power** of **Valentine's Meat-Juice** in **Quieting** the **Irritable Stomach, Aiding** the **Digestion, Restoring** the **Appetite** and **Sustaining** and **Strengthening** has been demonstrated by many **Medical Men** in the treatment of

Anaemia, Exhaustion and Debility.

Dr. R. Sarandeses, *Physician to the Provincial Hospital, Oviedo, Spain:* "I had occasion to use VALENTINE'S MEAT-JUICE on a member of my own family and with excellent results. It is most agreeable to the sick and well, is easily prepared and administered, and for the young anæmic constitutes a superior remedy."

Dr. Lenoble, *Surgeon in Chief, Military Ward of the Hospital D'Argentan, Argentan, France:* "The powerful reconstituent, VALENTINE'S MEAT-JUICE, brought about a great improvement in the condition of the sick and wounded, whose long stay in the trenches had made them particularly anæmic."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,
Richmond, Virginia, U. S. A.

S 13

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

MISCELLANY.

Rickets.—Carlos Jiminez Diaz (*La Pediatria Española*, June 30, 1923) believes that this disease is due to the following factors, 1. Lack of vitamin X in the diet, and lack of radiant energy. 2. A consequent slowing of the metabolic process. 3. Increased concentration of hydrogen ions in the organic media. 4. A break in the union of calcium with the proteins of the tissues.

White Mice and the Assay of Insulin.—Donald T. Fraser (*Journal of Laboratory and Clinical Medicine*, April, 1923) found that starved mice were susceptible to the intraperitoneal injection of insulin, and that mice fed immediately after its injection are tolerant to its effect. Fraser attempted to correlate the unit as determined by the use of rabbits with the unit as determined by the use of mice; 0.0025 c. c. was found to be approximately the equivalent of five (rabbit) units per c. c.

Complications of Labor.—Ogden F. Conkey (*Archives of Pediatrics*, April, 1923) concludes that the importance of hemorrhagic disease in the etiology of cerebral hemorrhage in the newborn has been exaggerated. Most intracranial hemorrhages are the result of trauma and can be explained satisfactorily by the mechanical features of labor. A better understanding and more skilful handling of the complications of labor will result in fewer birth injuries and hemorrhagic lesions of the brain.

Varicocele of the Broad Ligament.—R. Jahreiss in Augsburg (*Zentralblatt für Gynäkologie*, May 20, 1922) reports a case, which he diagnosed as a beginning tubal abortion. A consultant diagnosed the condition as a varicocele of the left broad ligament, but this diagnosis was not confirmed by an operation as the patient recovered spontaneously. After two years, the same patient presented a right tubal pregnancy with rupture, which resulted in a large retrouterine hematocele, from which she also recovered without operation.

Management of Diabetes Mellitus.—Charles W. McGavran (*Ohio State Medical Journal*, September 1, 1923) advocates a campaign against obesity, which according to Joslin is a large etiological factor in diabetes. A sugar tolerance test should be made on every obese patient; whether there be any diabetic findings or not the obese patient should be told of his danger and taught how to reduce. The sugar tolerance test should be repeated every six or twelve months. Insulin, while not curative, makes it possible for the severe diabetic to live but it in no way supplants dietetic treatment.

Significance of the Female Generative Organs in Renal Diabetes.—Heinz Küstner (*Zentralblatt für Gynäkologie*, July 29, 1922) finds that the excretion of sugar during pregnancy, with low blood sugar values (renal diabetes), is not the result of the impregnation of an ovum or of fetal metabolic changes, but it rather depends upon the function of the ovaries, especially the corpus luteum, which seems to be the exciting factor. This assumption is substantiated also by the fact that a renal glycosuria may occur in the premenstrual stage, that is, at the time of the existence of the corpus luteum. If these facts are borne in mind, renal diabetes may be considered as an early sign of pregnancy.

Stethoscopic and Röntgenographic Diagnosis of Pulmonary Tuberculosis in Adults.—John Tillman (*Hygiea*, June 15, 1923) reports observations on 300 patients in the Orup Sanatorium, the next largest tuberculosis hospital in Sweden. In twenty-five per cent. of the cases he finds fair agreement between the stethoscopic and the röntgen findings, whereas the röntgenogram gave a better result than the clinical diagnosis in 175 cases out of 243, and stethoscopy surpassed the röntgen diagnosis in only six cases. The author considers the röntgen procedure an extremely valuable auxiliary method which should be employed as often as possible.

Toxicity of Cocaine.—Ellison L. Ross (*Journal of Laboratory and Clinical Medicine*, July, 1923) undertook this work to determine whether adrenalin is an antidote for cocaine poisoning or a substance increasing its toxicity, using cats as subjects, and varying the rate of introduction of cocaine hydrochloride into the chloretoned animals. As the rate of introduction of cocaine increased the minimal lethal dose of cocaine first decreased and then gradually increased up to the end of the series. The conclusions reached are that the minimum lethal dose for cats varies with the rate of administration of cocaine; the absolute minimum lethal dose of cocaine hydrochloride for chloretoned cats is .0128 grams to the kilo of body weight, and that adrenalin markedly increases the toxity of cocaine.

Lipoids of Maternal and Fetal Blood at Conclusion of Labor.—J. Morris Slemons and Henricus J. Stander (*Bulletin of the Johns Hopkins Hospital*, January, 1923) in order to secure information regarding the activity of the placenta, which links the nutritional processes of mother and fetus, obtained and analyzed specimens from each simultaneously. A comparison of the two shows that the mother's blood contains much more fat, lecithin and cholesterol than does the fetal blood. The human placenta is impenetrable to fat and lipoids. Fetal fat must be synthesized from some material, probably glucose, which passes readily through the placenta, and is supplied by the mother in quantities proportionate to the demands of the fetus. No characteristic change in the blood fat or blood lipoids was found to accompany the development of eclampsia and allied intoxications of pregnancy.

Absence of Vagina and Hematometra With Unusual Operation.—C. D. Josephson (*Svenska Läkaresällskapots Förhandlingar* June 30, 1923) reports the case of a girl of fifteen who had menstrual molimina without flow, and investigation showed complete absence of vagina and above the symphysis pubis a large globular tumor, the uterus distended by accumulated menstrual fluid. This he remedied by making a suprapubic incision into the uterus, evacuating the contents and attaching the opened uterus to the abdominal wall, thus establishing a fistulous opening as exit for the menstrual flux, his object being to leave the patient in the possession of such genitalia as she had; and with entire satisfaction to the patient apparently, for throughout the eleven years that had passed since the operation the periodical functioning through the new channel was in no way disturbing to her. In spite of her infirmity the woman had contracted gonorrhœa during this period.

IN THE BRONCHIAL AFFECTIONS OF THE AGED,

an agent that will soothe the bronchial irritation and at the same time add resistance to weakened tissues, is clearly indicated.

CORD. EXT. OL. MORRHUAE COMP.
(HAGEE)

will accomplish these purposes, for which reason it is a frequently chosen agent in the relief of the chronic bronchial ailments of elderly persons. It soothes the bronchial mucosa and adds distinctly to the resisting powers of these old persons. And it is palatable, an advantage that permits its long continued use.

EACH FLUID OUNCE OF HAGEE'S CORDIAL OF THE EXTRACT OF COD LIVER OIL COMPOUND CONTAINS THE EXTRACT OBTAINABLE FROM ONE-THIRD FLUID OUNCE OF COD LIVER OIL, (THE FATTY PORTION BEING ELIMINATED), FOUR GRAINS CALCIUM GLYCEROPHOSPHATE, FOUR GRAINS SODIUM GLYCEROPHOSPHATE, ONE HALF GRAIN SALICYLIC ACID, (MADE FROM OIL WINTERGREEN), WITH GLYCERIN AND AROMATICS.

FREE FROM GREASE
AND THE TASTE
OF FISH.

Supplied in sixteen ounce bottles only. *Dispensed by all druggists.*

NEW YORK

Pathogenicity of Streptococci From Diphtheria Throats for Mice.—Louis Brody and Lloyd Arnold (*Journal of Laboratory and Clinical Medicine*, March, 1923) state that streptococci isolated from the throats of diphtheria patients do not seem to be pathogenic for white mice. Only two of twenty hemolytic strains tested showed virulence for the mice. The two strains had a limiting pH concentration of 4.7 and 4.6 respectively, being halfway between the pathogenic or human and the nonpathogenic or bovine type in this respect. The twenty viridans strains with a limiting pH of 4.2 to 5.0 were not pathogenic for mice. Streptococci from normal throats, the hemolytic strains giving a limiting pH concentration within the human or pathogenic range, were used as controls. These were also nonpathogenic for mice. The authors were unable to find any relation between the limiting pH concentration and the pathogenicity for mice.

Essential Factors in the Treatment of Intestinal Obstruction.—Thomas G. Orr and Russell L. Haden (*Journal of the Missouri State Medical Association*, October, 1923) emphasize the following points. 1. In treating acute intestinal obstructions, the mechanical obstruction, dehydration, starvation and toxemia should be emphasized as the four phases of the pathological process. 2. The mechanical obstruction should be relieved as soon as possible but the other three phases should be carefully considered in conjunction with its relief. 3. Dehydration should be overcome by the administration of three thousand c.c. or more of liquid every twenty-four hours during the acute illness. 4. The starvation should be met with the administration of sufficient glucose to produce a caloric value equal to or in excess of 1680 a day, which is the minimum for an adult of seventy kilos at rest. This may be given in the vein, under the skin and by rectum. 5. The toxemia which is the most important factor of the disease, may be combatted by giving sodium chloride in sufficient quantity to maintain the chlorides of the blood and urine at a normal level.

Posterior Gravity Drainage in Empyema: The Strategic Seat of Election.—In relating his experiences with posterior gravity drainage, John O'Connor (*British Medical Journal*, May 5, 1923), states that: 1. Drainage at the posterior inferior pleural angle is aided by gravity. Not a drop of pent up pus ever followed the removal of a wisp of silkworm gut for the purpose of changing or cleansing the same, even when the forcible cough test has been applied in the sitting or other posture. The dressings were continuously impregnated with discharge until the sinus closed. These two factors constitute socalled free dependent drainage. 2. The lung in all cases first expanded downward along the axillary wall, and invariably commenced its beneficent work by obliterating the outer segment of the cavity; from thence gradually continued its downward and inward expansion until the remaining sinus, which always passed inward toward the spine, was occluded. 3. A wisp of silkworm gut, while maintaining perfect drainage, does not cause any necrosis or pyogenic lining along its track irrespective of the one retained in situ. 4. The excision of rib may be an unnecessary adjunct when posterior gravity drainage is provided.

Action of Fibrolysin in Scleroderma and Dupuytren's Disease.—G. Tognini (*Revista Critica di Clinica Medica*, Florence, April 25, 1922), has found that the only contraindications to the use of fibrolysin are grave cardiac or renal lesions or tuberculosis. This drug is the sodiosalicylate of thiosinamin, and it is given intramuscularly in doses of two to three c.c. of a ten per cent. solution, two to four times a week. Both scleroderma and Dupuytren's disease showed distinct improvement under the use of fibrolysin in Tognini's hands.

Treatment of Essential Hemophilia With Maternal Serum.—Rezende Puech (*Annæs Paulistas de Medicina e Cirugia*, September-October, 1921), insists that true familial or essential hemophilia should not be confounded with temporary or symptomatic hemophilia or the hemorrhages of the newborn. He affirms that the intravenous administration of maternal blood serum is the best and most rational treatment of essential or true hemophilia. It is a method devoid of danger as it effectively prevents hemophilic accidents. Its action is both prophylactic and curative, and it can be given over long periods to obtain a definite cure.

Effect of Substances Having Hyperpyretic Action on the Fever Curve.—Paul Saxl (*Wiener klinische Wochenschrift*, April 9, 1923), asserts that chills can be produced by the intravenous injection in man by albuminous and nonalbuminous substances, whereas certain substances like serum, calcium chloride and others do not produce chills. By means of these artificial chills, every febrile curve may be interrupted without necessarily producing collapse. Both the artificial chill and that resulting from disease may be followed by either a high rise or a fall of the fever. If a hyperthermia is produced artificially (as with the injection of milk) without a chill, the subsequent fall in the febrile course is considerably slower, as compared with the rapid fall following a chill. In the septic chill there usually results a rise of temperature without any subsequent rapid fall. Intramuscular injections produce a less severe chill and therefore act more slowly.

Congenital Hypertrophy of the Pylorus.—One hundred and fifty-six children out of a series of two hundred and twenty-five with congenital hypertrophy of the pylorus observed by George F. Still (*British Medical Journal*, April 7, 1923) recovered and sixty-nine died. Operation is not necessary in every case, as is shown by the infants in whom the tumor and peristalsis gradually disappeared, and after weeks and even months of hovering on the verge of collapse, recovered completely without any special treatment except careful regulation and reduction of the diet. Of seventy-eight infants who were treated only by lavage, forty-three recovered and thirty-five died. The author believes that he is justified in retaining this method of treatment in certain cases. If the infant is breast fed, it is best to resort to operation immediately, so that the breast feeding may be continued with an interruption of only forty-eight hours. Of one hundred and eight infants treated by forcible dilatation, eighty-six showed good results; twenty-two infants of this group died. The Rammstedt operation was successful in eighteen out of twenty-nine cases. The author's favorite procedure is dilatation.

After all the most important thing is to relieve the distressing symptoms of digestive disorders first and then apply the systematic remedies for proper correction of functional defects. Do you know that thousands of doctors recommend six (6) Bell-ans dissolved in a glass of hot water for immediate relief in digestive disorders?

Bell-ans gives results; that is why it is now universally used.

To Safeguard the Nose, Mouth and Throat Against Acute Infections

has been conclusively shown to be the main consideration in the prevention of the graver respiratory ills, such as pneumonia, bronchitis, sinus and middle ear disease, and so on, that make so many practitioners of medicine dread the advent of cold weather.

Immediate attention to the mildest cold or inflammation of the upper air passages, with routine cleansing of the mucous membrane, constitutes the most important detail in accomplishing the foregoing, and no antiseptic at the physician's command today assures naso-oral prophylaxis with such certainty and gratifying freedom from harmful or disagreeable effects as

Dioxogen

$H_2 O_2$ 12v

Of course, Dioxogen, like any local measure, must be used thoroughly and made to reach every part of the naso-oral mucous membrane. But owing its action entirely to the large volume of pure oxygen it gives off when brought in contact with bacteria, and being absolutely free from toxic or irritating properties, it can be used as frequently and extensively as conditions may require.

Employed, therefore, according to the directions given herewith, and in conjunction with the systemic and supportive treatment dictated by the physician's judgment, every confidence can be placed in the ability of Dioxogen not only to control nose and throat infections, but also to prevent the development of the complications and sequelae that form their greatest menace.

The Dioxogen Treatment of Nose and Throat Colds

At the first sign of a nose and throat cold, the mucous surfaces should be swabbed thoroughly, though gently, with cotton pledgets saturated with Dioxogen, diluted one part to three of warm water, especial care being used to reach back of the faucial pillars. If the condition indicates a severe infection, this swabbing by the medical attendant should be done twice a day. In addition to this, the patient should spray the nose and throat every hour or two with Dioxogen in a strength of four to six teaspoonfuls to a half glass of warm normal salt solution. The rapid control of the infection means grateful relief and the effectual prevention of complications and sequelae.

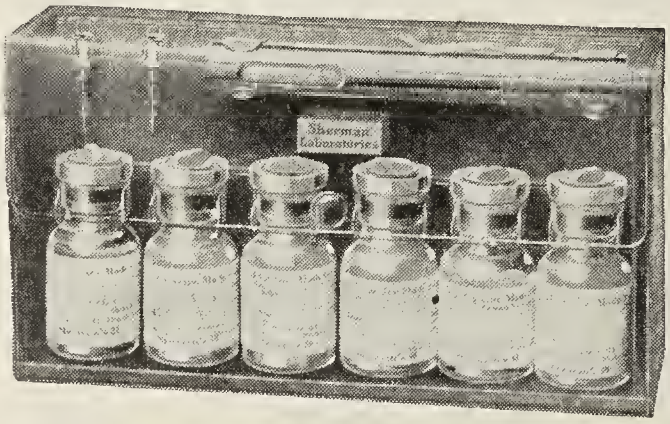
Does Heat Injure Vaccines?

THE recommendation of most Biologic Manufacturers is that their products be kept on ice. If room temperatures are deleterious to these vaccines what happens to them when they are heat sterilized? Sherman's Vaccines are sterilized without heat.



On presentation of this advertisement to your druggist you will be entitled to this genuine leather case arranged to hold six 12½ c. c. vials, and an all glass self-sterilizing syringe with two gold tempered needles gratis with your order for any six vials of Sherman's Vaccines. If your druggist can not supply you we will be pleased to furnish your requirements until local distribution satisfactory to you can be arranged.

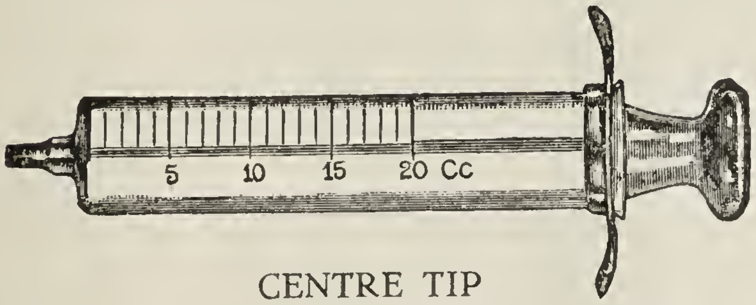
ENDO
LUER SYRINGES

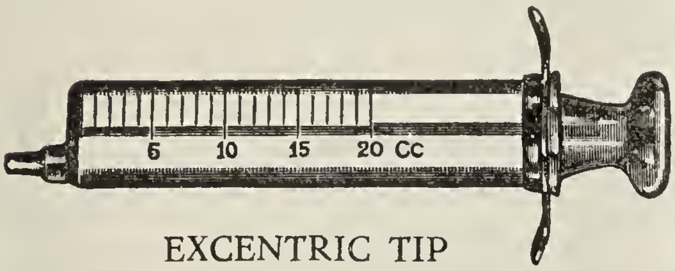
"ENDO" LUER SYRINGES are made by the manufacturers of Endo-Intravenous Solutions and may be had from them or from their duly appointed distributors.

Their sole purpose is to furnish the Medical Profession using Endo-Intravenous Solutions, a syringe that is durable and dependable, at a reasonable cost and sure to add to the effectiveness and ease of direct medication.



CENTRE TIP

2 cc	$ .90	10 cc	$1.75
5 cc	1.25	20 cc	2.25
30 cc	$3.00		



EXCENTRIC TIP

2 cc	$1.25	10 cc	$2.00
5 cc	1.75	20 cc	2.75
30 cc	$3.75		

Made from specially drawn "pot" glass, diamond-ground and hand-fitted, they are guaranteed not to leak at any point and at the same time maintain smoothness of action. The hair-line engraved scale insures absolute accuracy of reading and dosage.

If any parts of our syringes should break, replacement will be promptly made at cost of material and labor. They are guaranteed to withstand vigorous use and sterilization.

ENDO-LUER NEEDLES made from the best carbon spring steel. Points are hand ground with keen cutting edge. Guaranteed against leakage or breakage in service.

Gauge 22-26—⅝″ to ¾″ ... $1.00 doz.
Gauge 18-21—1″ to 1½″ ... $1.50 doz.

OFFICE TECHNIC

THE BEST

The Best always bear a price in keeping with the care, skill, time, cost and risk attending their invention and manufacture.

The Best, when justly estimated, are the cheapest. They are attended with less profit to the producer than those which everybody calls cheap.

"A composition for cheapness and not for excellence of workmanship is the most frequent and certain cause of the rapid decay and entire destruction of the arts and manufacture". ......*Ruskin.*

The conscientious physician uses only the best, the standard.

KELLOGG COMPANY
BATTLE CREEK, MICH. AND TORONTO, CAN.
Kellogg's
BRAN

KELLOGG'S BRAN

for the relief of constipation

In mild or chronic constipation cases, the value of bran, as you know, lies in its bulk. Distention of the intestine provides improved peristaltic action, which gives the anticipated relief.

Physicians everywhere are prescribing Kellogg's Bran and advocating its daily use at the family table, because Kellogg's is ALL BRAN. The point is made that the required bulk is not obtainable in foods with a partial bran content. Relief would be delayed and suffering and annoyance prolonged.

The mechanical action of Kellogg's Bran is exceedingly positive because it is ALL BRAN and it may be prescribed with confidence in both chronic and mild cases.

Patients find Kellogg's Bran delicious in flavor and edibility. Kellogg's should not be compared with common bran!

Physicians are asked to mail a request card to Kellogg Company, Battle Creek, Mich., and a full-sized package of Kellogg's Bran will be forwarded without obligation.

An Analysis of

Kellogg's BRAN

Aside from its regulatory value, Kellogg's Bran commands attention as one of the most valuable foods known. Read this analysis:

The Tooth Paste

That millions, the world over, now employ

Pepsodent is now used the world over. It is a leading dentifrice in some 50 nations now, and largely by dental advice.

It is based on three major requirements, urged by modern dental authorities.

1—Mildly acid reaction

The acidity combats mucin plaque. It increases the salivary flow and increases its alkaline index as well as its ptyalin index.

Investigation shows that peoples who eat much fruit of an acid character are notably free from caries. Pepsodent is designed to regularly bring the essential effects, such as are produced by acid fruits.

2—No soap, no chalk

Soap and chalk mean an alkaline tooth paste. They bring the reverse of the Pepsodent effects. They reduce the fluidity and flow of the saliva; they reduce its alkaline index; they reduce its starch digestant; they weaken Nature's tooth-protecting agents in the mouth.

3—Right polishing

The polishing agent in Pepsodent is a blend of finely powdered calcium phosphate and calcium sulphate. It is soft, mild, harmless, yet efficient. Exhaustive tests have proved it the ideal polishing agent.

Omission of soap—a lubricant—makes this agent somewhat conspicuous. But it is far softer than enamel. In convincing tests natural teeth have been brushed with it hundreds of thousands of times without sign of ill effect.

Ask information

If any questions arise about Pepsodent, ask for information. We publish much scientific data. Competent men of long experience are here to answer every question.

The coupon will bring you a tube for testing.

Antiphlogistine poultice, some hours after application to inflamed area. Centre is moist, where exudate has been drawn from the congested tissues. Periphery, covering normal surrounding tissues virtually dry.

This chart shows the Osmotic action of Antiphlogistine

DIAGRAM represents inflamed area. In zone "C" blood is flowing freely through underlying vessels. This forms a current away from the Antiphlogistine whose liquid contents therefore, follow the line of least resistance and enter the circulation through the physical process of endosmosis.

In zone "A" there is stasis, no current tending to overcome Antiphlogistine's hygroscopic property. The line of least resistance for the liquid exudate is therefore in the direction of the Antiphlogistine. In obedience to the same law, exosmosis is going on in this zone, and the excess of moisture is thus accounted for.

Antiphlogistine generates and retains heat upwards to 24 hours

Due to the chemical reaction which goes on during Osmosis between the c. p. glycerine of Antiphlogistine and the water of the tissues, Antiphlogistine keeps up a steady heat generation.

This sustained heat is invaluable; relieving congestion by increasing superficial circulation, stimulating the cutaneous reflexes, and causing contraction of the deep-seated blood vessels.

Used by hundreds of thousands of physicians the world over.

Antiphlogistine stands alone as a non-toxic, non-irritant abstractor of fluid exudates in superficial inflammations. It relieves deep-seated congestion by inducing superficial hyperemia, through its inherent hygroscopic property, and without irritation.

Let us send you our free booklet "The Pneumonic Lung." Address The Denver Chemical Company, Dept. A, New York, U. S. A. Branches: London, Sydney, Berlin, Paris, Buenos Aires, Barcelona, Montreal.

Diphtheria

Treatment

Diphtheria Antitoxin

For treatment of acute cases and to produce immediate temporary immunity.

Dose: 1000 to 20,000 Units.

Supplied in aseptic, glass syringes, ready for use.

Prevention

T-A. Mixture (Diphtheria Toxin-Antitoxin Mixture)

To create lasting immunity, which develops in about six weeks, and is believed to continue almost indefinitely.

Dose: Three injections of 1 Cc. each, at seven-day intervals.

Supplied in three 1-Cc. ampuls and in 10-Cc. vials.

Susceptibility

Schick Test Toxin (Diphtheria Toxin for Schick Test)

To determine susceptibility to DIPHTHERIA.

Dose: 0.1 Cc., injected between the layers of the skin.

Supplied in packages containing one hermetically sealed tube of undiluted DIPHTHERIA TOXIN, with one 5-Cc. vial of Saline Solution, sufficient to make at least forty tests.

Schick Test Toxin Control

Diluted DIPHTHERIA TOXIN, attenuated by heat, to be used as a control for the MULFORD SCHICK TEST TOXIN.

Dose: 0.1 Cc.

Supplied in 5-Cc. vials, sufficient for at least forty tests.

THE PIONEER BIOLOGICAL LABORATORIES

The delightful Homestead is connected with the thermal bath establishment by an enclosed viaduct.

The Radio-Activity of the Mineral Waters at Virginia Hot Springs

It is well known that the high amount of radio-activity in the waters of Carlsbad, Gastein, etc., explains to a certain extent the favorable therapeutic results in the treatment of gout, chronic and subacute rheumatism, and metabolic diseases.

Professional analyses of the waters at Virginia Hot Springs have determined a high amount of radio-activity. Several of the springs are among the strongest radio-active springs in the world.

The facilities for hydrotherapeutic treatment, modern and complete, are under professional direction. Accessory facilities include a full set of Zander apparatus and the Tyrnauer electrically-heated apparatus for giving local superheated dry air baths.

Mild, invigorating atmosphere and surroundings of great beauty, 2500 feet up in the Alleghanies, invite outdoor recreation — walking, horseback riding, golf, etc. The exercise is carefully advised to suit the strength of the individual.

Open all the year

Illustrated and descriptive literature, together with literature prepared especially for the profession, sent on request.

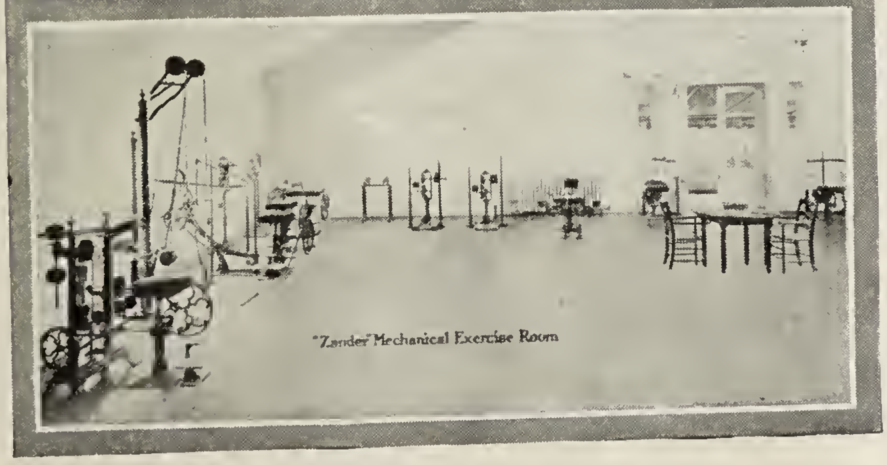
Christian S. Andersen, Resident Manager
The HOMESTEAD, Hot Springs, Virginia



"Zander" Mechanical Exercise Room

The Human Factor

Human nature is perhaps the most variable factor with which the physician has to deal.

If people could be made to go to their physicians periodically for a physical examination, a great deal of chronic illness could be averted.

But the average human is a careless mortal.

The National Bureau of Analysis overcomes this careless tendency by systematizing the matter of periodical urinalysis for its subscribers so that the submission of a specimen becomes almost automatic and devoid of all trouble.

By this means the Bureau is enabled to keep a check on the condition of its subscribers, as revealed by urinalysis, and when some disorder is evidenced to notify the subscriber to immediately consult his or her own physician.

This results in the Bureau referring to the physician every year thousands of people who otherwise would neglect their condition until it became chronic.

In this way, we perform a real service to both the physician and his patient.

Our laboratory is conducted in the most scientific and ethical manner, and we invite investigation and inspection on the part of any regular medical man.

Medical Books Make Splendid Christmas Gifts

WHY not give that doctor friend or relative of yours a good medical book as your Christmas gift? Whether he is a young beginner or has been many years in practice he will certainly appreciate it as much or more than anything else you can think of. No physician can have too many professional books. Below we make a few suggestions. If you are in doubt better choose the Dictionary. Any doctor will be delighted to receive the newest and most up-to-date medical dictionary. Hippocrates is another safe selection. Send check with order and one of your cards to enclose with the book, or we will put your name on the wrapper if you say so. We pay postage. We will exchange any book if returned before January 5th, postage paid. *Descriptive catalogue and special advice on request.*

For Any Physician or Surgeon:—

Stedman's Practical Medical Dictionary. New seventh edition. A splendid big book of 1160 pages, well illustrated, flexibly bound in red, with thumb index—$7.00. *Excellent gift also for a nurse.*
Adams—Works of Hippocrates—$6.00.
Arderne—De Arte Phisicali et de Cirurgia (1412) translated by Sir D'Arcy Power—$4.00.
Comrie—Selected Works of Thomas Sydenham, M. D.—$3.00 (1624).
Hale-White—Selected Passages from Laennec—$3.75.
THE GIFT SUPREME—Reference Handbook of the Medical Sciences. First and only complete medical encyclopedia in the English language. Eight large volumes, thousands of illustrations. Almost a complete medical library in itself. Subscription work. New fourth edition. Price $80.00. Special check-with-order price for Christmas $75.00. Express prepaid. *Ask for Prospectus.*

For the General Practitioner:—

Bell—Principles of Gynecology, Third edition—$10.00.
Bell—The Sex Complex, Second edition—$6.00.
Bourne—Synopsis of Midwifery—$3.50.
Cabot—Physical Diagnosis, Eighth edition—$5.00.
Einhorn—Diseases of the Stomach—$4.50.
French—Index of Diagnosis, Third edition—$12.00.
Herman—Difficult Labor, Sixth edition—$5.00.
Hutchison—Food and Dietetics, Fifth edition—$5.00.
Hutchison and Sherren—Index of Treatment—$12.00.
Jellett and Madill—Manual of Midwifery—$10.00.
Kerr & Ferguson—Obstetrics and Gynecology—$10.00. *Nearly ready. Christmas delivery sure.*
Leftwich—Index of Symptoms—$4.50.
Luke—Manual of Physio-Therapeutics—$6.00.
MacKenna—Diseases of the Skin—$6.50.
May—Manual of Diseases of the Eye—$3.50.
Medical Record Visiting List and Physicians' Diary. Size for 60 patients per week—$2.00; 90 patients—$2.50. Name in gold—25c, with address—50c. *Handsome and practical gift.*
Milligan & Wingrave—Diseases of the Ear—$3.50.
Muthu—Pulmonary Tuberculosis—$4.50.
Russell—Stomach and Abdomen—$4.00.
Savill—System of Clinical Medicine—$9.00.
Short—Index of Prognosis—$12.00.
Walker—Dermatology—$7.00.
Walters—Treatment of Tuberculosis—$4.00.
Watson—Food and Feeding, Second edition—$5.00.
Wheeler—Handbook of Medicine (Jack)—$4.00.
Wilde—Gout, Rheumatism and Arthritis—$3.50.
Williams—Minor Maladies—$3.25.

For the Surgeon:—

Adams—Acute Abdominal Diseases—$6.00.
Beesly & Johnston—Surgical Anatomy—$6.50.
Chetwood—Urology—$8.00.
Chiene—Handbook of Surgery—$4.50. *Just Out!*
Doyen—Surgical Therapeutics and Operative Technique. Three large volumes, $25.00, 2263 pages, 2975 illustrations.
De Quervain—Clinical Surgical Diagnosis—$14.00.
Groves—Synopsis of Surgery, Sixth edition—$4.50.
Herbert—Glaucoma—$3.00.
Jones and Lovett—Orthopedic Surgery—$9.00.
Lejars—Urgent Surgery—$16.00.
McKay—Lawson Tait, His Life and Work—$7.50.
Mummery—Diseases of the Rectum and Colon—$8.00.
Pye—Surgical Handicraft, Eighth edition—$6.50.
Rose and Carless—Manual of Surgery—$9.00.
Schmieden and Turnbull—Operative Surgery—$6.50.

For the Eye, Ear, Nose and Throat Specialist:—

Axenfeld—Bacteriology of the Eye—$5.00.
Grimsdale and Brewerton—Textbook of Ophthalmic Operations, Second edition—$5.50.
Lake—Diseases of the Ear, Fourth edition—$3.00.
Lamb—Diseases of the Nose, Throat and Ear—$3.50.
Laurens—Oto-Rhino-Laryngology—$4.50.
Mann—Textbook of Tracheo-Bronchoscopy—$9.00.
May—Diseases of the Eye, Tenth edition—$3.50.
Milligan & Wingrave—Diseases of the Ear—$3.50.
Porter—Diseases of the Nose, Throat and Ear—$4.00.
Syme—Diseases of the Nose, Throat and Ear—$2.75.

For the Neurologist and Psychiatrist:—

Bianchi—Mechanism of the Brain—$5.50.
Brown—Advanced Suggestion—$3.50.
Cobb—Neurasthenia—$3.75.
Core—Functional Nervous Disorders—$6.00.
Dana—Textbook of Nervous Diseases—$6.50.
Jones—Treatment of the Neuroses—$3.75.
Jones—Psycho-Analysis—$8.00.
Kelynack—Defective Children, Second edition—$4.00.
Somerville—Practical Psycho-Analysis—2.50.
Tredgold—Mental Deficiency—$6.00.

For the Pediatrist:—

Burnet—Diseases of Children—$3.00.
Chapin and Pisek—Textbook of Diseases of Children, Fourth edition—$4.50.
Kelynack—Defective Children, Second edition—$4.00.
Von Reuss—Diseases of the New-Born—$12.50.

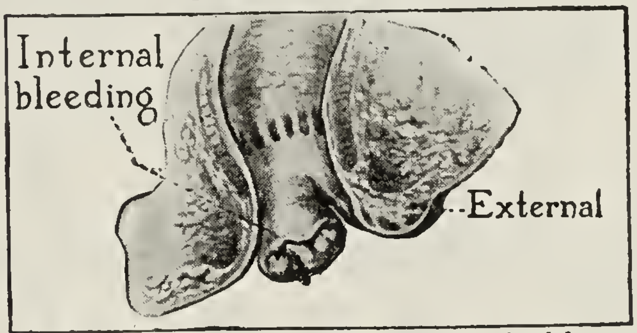
Proctitis

Fissure of anus

Cryptitis (focus of infection)



Internal and external hemorrhoids.

LUBRICATION THERAPEUSIS
IN RECTAL AND ANAL PATHOLOGY

PROCTITIS: According to a noted proctologist, inflammation of the rectal mucosa is much more common than is generally thought. The indications for treatment are to produce a soft evacuation and to lubricate and soothe the bowel wall. Nujol accomplishes this and also reduces the time during which the fecal mass is held in contact with the inflamed mucosa, thus quickening the healing of the membrane.

FISSURE: The dry, hard feces when forced over the delicate mucous membrane of the anal canal cause it to erode, leaving an open wound. Nujol softens the feces and lubricates the intestine. Thus it prevents fissure formation or encourages healing by preventing irritation and infection.

HEMORRHOIDS: Rectal inflammation and fecal impactions prevent the proper flow of venous blood into the portal circulation. This is accentuated by the absence of valves in the rectal veins and man's upright position, but particularly by straining at stool. Nujol, by its softening, lubricating action, enables the feces to be evacuated without straining. Thus, by removing one of the conditions which causes and aggravates hemorrhoids, Nujol brings comfort and relief to the patient, often leading to ultimate disappearance of the trouble.

CRYPTITIS: A frequently overlooked cause of painful defecation and a source of systemic infection. The hard fecal lumps are kept soft by the regular administration of Nujol. Nujol also forms a lubricating coat over the crypt, thus favoring healing and relieving the pain.

Nujol, the ideal lubricant, is the *therapeutic common denominator* of all types of constipation. Microscopic examinations show that too high a viscosity fails to permeate hardened scybala. Too low a viscosity tends to produce seepage. Exhaustive clinical tests show the viscosity of Nujol to be physiologically correct and in accord with the opinion of leading medical authorities.

Nujol

Guaranteed by NUJOL LABORATORIES, STANDARD OIL CO. (NEW JERSEY)

COMBINES the delightful qualities of effervescence with the well-known digestive properties of Peptenzyme.

The powerful and effective action of Peptenzyme, supplemented with the tonic and refreshing effects of effervescence, thus insures both

PERMANENT BENEFIT AND PROMPT RELIEF

in gastralgia, nervous and fermentative dyspepsia, flatulence, atonic indigestion, and to relieve the gaseous fermentation that usually causes so much discomfort in digestive disorders.

It is palatable to the nth degree and gives the physician a cooling and refreshing beverage, free from any hint of medicine, yet pregnant with therapeutic value.

Your Patients' Pain
can be relieved by

PHENALGIN

First — Promptly and effectually.
Second — Without the least danger of causing a drug habit.
Third — No special blanks are needed in prescribing Phenalgin, and no special records have to be kept.

Phenalgin in the great majority of cases makes the opiates, with all their dangers and inconvenience unnecessary.

Its constantly increasing use since its introduction over a quarter of a century ago is the logical result of its efficiency as a pain reliever.

THE HARROWER LABORATORY, Inc.
Glendale California

ORGANIZED 1912

Radium Institute of New York

323 Riverside Drive—at 104th Street
Phone Academy 6100

An institution thoroughly equipped for the application and study of all types of radium therapeutics, and allied measures of treatment. Patients may be referred on orders from any physician or institution. Full medical and surgical hospital care.

PHYSIO-THERAPY DEPARTMENT

This important branch of the Institute is open for inspection of physicians and for the reception of patients. Electro-magnetic therapy of the most improved and modern type is administered under the direct supervision of a qualified staff. Cabinet electron emanators of deep penetration, adapted to the requirements indicated in the extreme chronic manifestations of Arthritis, Neuritis, Neurasthenia, Arterio-sclerosis, Cardio-vascular degenerations and the early senile period. Superior facilities offered the physician, enable him to check up the metabolism of his patient and co-operate in securing a more scientific application of physio-therapeutics. Particular attention is given to secure the complete comfort and privacy of each referred patient. Literature and special information on request. Consultation with the physician in charge is desired before patients are accepted.

The Management of an Infant's Diet

Malnutrition, Marasmus, Infantile Atrophy, Athrepsia

Mellin's Food	**8 level tablespoonfuls**
Skimmed Milk (1% fat)	**9 fluidounces**
Water	**15 fluidounces**

This mixture contains 56.61 grams of carbohydrates, thus supplying material that is utilized rapidly for heat and energy. The predominating carbohydrate is MALTOSE, which has the highest point of assimilation of any of the sugars, is immediately available as fuel and may be safely given in comparatively large amounts. The daily intake of protein from the employment of this formula is 15.54 grams, an amount calculated to be sufficient to replace depleted tissues and to provide for new growth. There is present in the mixture 4.32 grams of salts for replenishing inorganic elements.

The suggested modification furnishes nutrition in keeping with the character and amount of food elements best adapted to the particular demands of infants in an extreme state of emaciation and serves well as a starting point in attempting to meet the nutritive requirements of these undernourished babies.

Mellin's Food Co., 177 State Street Boston, Mass.

Genito-Urinary Diseases

PROTARGOL

In acute and chronic gonorrhea Protargol is considered by many urologists an essential feature in the routine treatment. Acute cases respond quickly to weak solutions, which are well borne and economical.

ALYPIN

For local anesthesia of the genito-urinary tract in cystoscopy, instrumentation and operative work, Alypin has proved safe, prompt and efficient.

HELMITOL

Where an internal urinary antiseptic is required, as in cystitis, pyelitis and urethritis, Helmitol has been found to be agreeable of administration, excellently tolerated and satisfactory in effect.

"METZ MADE MEDICINALS"

NEOSALVARSAN

The practitioner who employs Neosalvarsan is reinforced in his judgment by more than 12 years of carefully controlled clinical experience. In the manufacture of American Neosalvarsan we have faithfully preserved the processes leading to the production of the original Ehrlich "914," unsurpassed in therapeutic potency.

The lowered prices of this therapeutic sufficiency herewith appended show our mindfulness of our obligations to the profession and the public.

0.15 gram	$ .60 per ampule	0.6 gram	$ .80 per ampule
0.3 gram	.65 per ampule	0.75 gram	.90 per ampule
0.45 gram	.70 per ampule	0.9 gram	1.00 per ampule

SULPHARSPHENAMINE

Sulpharsphenamine, one of the earlier Ehrlich arsenicals, intended for intramuscular use, is manufactured by us. Prices range from 50 cents per ampule for 0.05 gram size to 80 cents per ampule for the 0.6 gram size.

H·A·METZ LABORATORIES, INC.
122 HUDSON ST. NEW YORK

COUGHS

It is important that each form of cough be treated according to its origin and effect, and as a reliable guide to the physician, we suggest the following time tried preparations.

BECHOL, an elixir white pine compound, especially indicated in coughs resulting from bronchial and laryngeal conditions.

CANNABIS COMP., most useful in persistent coughs, resulting in restlessness and high nervous tension.

CASTAFLORA, of especial service in whooping cough and other coughs of a spasmodic nature.

MENTHYPHEN, especially efficacious in diseases of the respiratory organs, and of specific value in coughs due to aggravated catarrhal conditions.

Complete literature and samples of any of these preparations will be supplied upon request.

CAMPHO-PHENIQUE TRADE-MARK

Campho-Phenique

A POWERFUL GERMICIDE

A host of germicides command attention through sheer merit. Any one that stands out among them with particular conspicuousness does so because of exceptional value and because it has demonstrated its superior worth beyond question.

CAMPHO-PHENIQUE rules among its kind because it is superior to them in actual searching tests. As a germicide CAMPHO-PHENIQUE is positive in effect, economical and uniform in action.

As a first aid dressing CAMPHO-PHENIQUE is the logical choice, owing to its continuous germicidal action and anodyne effect.

The properties possesed by Campho-Phenique make it the ideal dressing for all surgical wounds. It prevents infection and hastens healing.

Keep a supply of CAMPHO-PHENIQUE on hand for all antiseptic purposes.

Samples mailed on request.

Campho-Phenique Co., St. Louis, Mo., U. S. A.

IMPROVEMENT OF DIPHTHERIA ANTITOXIN

NOTWITHSTANDING the vast fund of experience and information which has been gained through the many years in which Diphtheria Antitoxin has become established in medical practice, our knowledge is nevertheless steadily increasing and improvements continue to be made in the method of manufacture.

In the early days of serum therapy the standardization of antitoxin was a haphazard proposition, and even the tests utilized for safeguarding its purity left much to be desired. All that is a thing of the past. The standardization of antitoxin is now a definite and accurately controlled procedure, so that its potency, as expressed in antitoxic units, is a certain guide to the physician in determining dosage. Thoroughly dependable tests for insuring the freedom of the product from bacterial contamination or toxic substances of whatever nature have also been developed.

During recent years research effort has largely been directed toward increasing the concentration of antitoxin —getting the therapeutic dose in a smaller bulk and eliminating unnecessary solid material, especially proteins. An antitoxin thus refined has obvious advantages. The smaller quantity is easier for the physician to inject and less painful to the patient. Even more important, however, is the elimination of unnecessary albuminous substances which in certain patients may cause protein toxemia.

It is now possible, by methods of chemical precipitation, to so concentrate diphtheria antitoxin as to make a given volume many times as potent as the same amount of serum freshly separated from the blood of the treated horse. This is accomplished by precipitating the serum globulin, a constituent of the serum with which the antitoxic element is closely identified. Various methods of carrying out this concentration have been developed, the results of which vary—not only in the degree of the concentration, but also in the physical characteristics of the antitoxin thus obtained. It is very important that the concentration be effected without increasing the viscosity of the globulin to a degree sufficient to delay absorption when administered to the patient. Absorption is an important factor in the clinical response to antitoxin, whether the injections are given subcutaneously or intramuscularly; and delay in absorption is obviously a serious disadvantage.

The methods employed in the biological laboratory of Parke, Davis & Co. furnish a practical solution to this problem. The resultant antitoxin has a high concentration, a low content of protein in comparison with its unit strength, and on injection is absorbed with great rapidity.

To safeguard the potency of the product, every lot contains 40 per cent excess units at the date of issue—more than enough to insure the full labeled potency within the period of use for which it is dated.

Five sets of purity tests are carried out with every lot of antitoxin, to preclude the possibility of any contamination of the serum.

The development and rigid enforcement of these methods has given to the medical profession an antitoxin of high excellence, the purity and dependability of which are beyond all question.

PARKE, DAVIS & COMPANY
DETROIT, MICHIGAN

AMENORRHEA

DYSMENORRHEA

MENORRHAGIA

usually respond to treatment with

HORMOTONE

which acts directly through the endocrine apparatus concerned in the menstruation process.

Dose: 1 or 2 tablets three times daily.

G. W. CARNRICK CO.

420 Canal Street New York, N. Y.

Sluggish Bowel Action in Childhood

is usually due to errors in feeding. Subjecting these fundamentals to the customary careful correction,

INTEROL

may be administered coincidentally to relieve the immediate condition.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

Sample and Interol brochure on request.

"The One Cigarette Sold the World Over"

E AND A

Tonsilitis and Laryngitis

During this season of the year the physician is often called upon to prescribe a remedy for throat infection. We suggest you use **BORO-FORMALIN,** a powerful non-toxic, non-irritant, antiseptic solution.

As a gargle or spray diluted with 5 parts of water, it destroys the micro-organisms that find a lodging place in the mucous membrane of the larynx and pharynx. It may also be used by applying it direct to the parts affected by means of the cotton applicator.

BORO-FORMALIN is composed of Boro-Salicylic Glycerole, Benzo-Resorcinol, Menthol, Thymol, Eucalyptol and 2 pro mille of Formalin. It is miscible with water, alcohol or glycerin in any proportion, has a pleasant aromatic odor and a pungent taste.

We suggest you give it a trial in your next case of Tonsilitis, Laryngitis or Pharyngitis. You will be pleased with the result. A sample is yours for the asking.

"HERRADORA" INJECTIONS.
Intravenous — Intramuscular

RHEUMATISM

The fundamentals of oral or intravenous medication must be based on sound and rational therapeusis. While isotonicity is a pharmacological achievement, that is not all, as it is axiomatic that no one or two drugs used singularly will cover the *synergistic circle* in a varied and complex symptomatology.

As in oral medication, a *complete formula* is required for intravenous administration. This we offer in our ampoulized solutions for a *distinct* and *individual* treatment of acute, subacute and chronic RHEUMATISM.

Our preparations are sold on merits and we are convinced after years of experience that one or two injections will bring results that will justify its further use.

They are made for both *intravenous* or *intramuscular* injection. Should *perivenous infiltration* occur it is not productive of destruction of tissues or abscess formation. They are entirely *antiseptic.*

SOD. IODIDE-SALICYLATE

PARALLEL RAYS
PENETRATE DEEPLY

The rays of the Thermolite penetrate deeply into tissue, just as a searchlight beam penetrates space; because they *are* parallel.

Thermolite rays carry radiant light and heat well below the surface, thus relieving even deep seated congestion, with its consequent pain, and promoting metabolism.

There is no focal spot to burn or blister—even in prolonged application.

Progressive physicians are using Thermolite in place of convective heat, such as hot water and other superficial applications, as it is more efficient and convenient, gives greater penetration, besides having the decided advantage of combination with light.

Thermolite
TRADE MARK

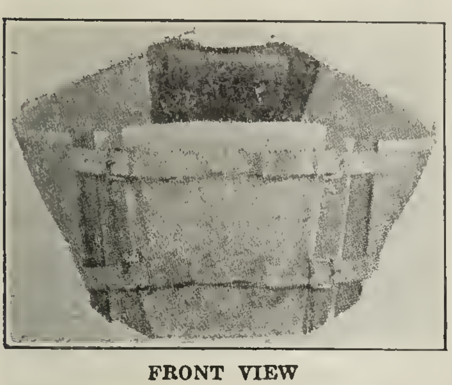
Sacro-Iliac Belts

"THE MAYO"



FRONT VIEW

The Mayo Sacro-Iliac Belt is the most satisfactory appliance for controlling and relieving Sacro-Iliac sub-luxation. This belt has now reached an advanced stage, and we are bringing it to the attention of the Medical Profession, for the recognition that it deserves.

This Belt is constructed of heavy six-inch orthopaedic webbing, with a separate abdominal plate, providing for its correct adjustment, with a suitable sacral pad attached and covered with chamois. This appliance gives the desired support when properly adjusted.

The belt should be tightly buckled in front on each side, before direct pressure is secured over the sacrum by the lacings which are provided at that point. Examination of the cuts will give a good idea of its construction and superior points.

The price is $12.00. Take measurement around the hips three inches below the Iliac crests, or directly over the trochanters.

Private Institutions and Sanitariums

STAMFORD HALL
(DR. GIVENS' SANITARIUM)
STAMFORD, CONN.
Phone 70

A private sanitarium for the scientific treatment of nervous and mental diseases, drug addiction and alcoholism, and general invalidism.

The sanitarium is completely equipped for the care, comfort and treatment of patients and offers exceptional facilities in hydro and electro therapy and massage. Arranged on the cottage plan. Separate cottages or suites if desired. Any accommodations required can be furnished. Particular attention is paid to the amusement of patients. *Occupational work,* conducted under the supervision of a skilled director, embraces *needle work, bead work, weaving, basketry,* and all methods of diversion in general use. There are also moving pictures and entertainments for convalescent patients. Golf, tennis, croquet, clock golf, volley ball, etc.

Special facilities are offered for the care of *elderly people* who need comfortable homelike surroundings and good nursing attention.

Located in a beautiful natural park of 100 acres where numerous detached buildings insure privacy. Fifty minutes from Grand Central Station on the New Haven Railroad.

FRANK W. ROBERTSON, M.D., the President and Medical Director, can be seen at his New York Office, 412 West End Avenue, Cor. 80th St. on Mondays, Wednesdays or Fridays, at noon. New York Telephone Endicott 7796.

—AT A MODERATE COST!

RADIUM EMANATION

This organization supplies a service whereby you can secure at any time Radium Emanation—RADON—in the form that you want, "seeds," tubes, plaques, etc.—at a cost surprisingly *low*. This service places in your hands the ability to use the most modern Radium Therapy. With the Emanation we loan you applicators, instruments and screens. Our Medical Staff is available at all times for consultation as to technique, dosage and screenage.

Literature, prices and Dr. William Duane's, Ph.D., D.Sc., of Harvard University, our Consulting Physicist, brochure "The Use of Radium Emanation in the Treatment of Disease," sent upon request.
